special dysentery wards with separate latrines and disinfecting apparatus for the hospitals, hospital-dysentery is stated to have become uncommon. The senior medical officer would add a separate dysentery convalescent gang, as an additional means of preventing the spread of infection. Efforts are also being made to ensure that clothes worn by the prisoners are thoroughly dry. The frequency of self-induced dysentery is noted, and a list of the principal irritants taken with the object of inducing this disease is given. At every station there is a boiler, from which a plentiful supply of boiled drinking water is available. Reforms were carried out in the dieting and cooking, in the milk supply, and in the vegetable ration. Vegetables were divided into first class and second class in respect of their antiscorbutic value, and orders were issued that at least one-third of the rations should be of the first class. Scurvy is stated to be rare in the settlement now-a-days, and the gum affections which occur are put down to malaria and to the fact that prisoners do not pay sufficient attention to the cleanliness of their mouths and teeth. All the measures enumerated are good on paper but the result depends on how they are carried out. In the meantime the statistics of sickness and mortality do not indicate even the beginning of success.

Burma.—The health of the Burma prisoners, like that of the general population, was better than in the preceding years, the admission and constantly sick ratios being the lowest on record. Occasional overcrowding occurred in district jails, but was relieved by transfer. Boiling and permanganating of water is carried out in all the jails of the province. There is room for improvement in the method of distributing water in some of the jails; but in the central prisons and in some of the district jails it is pumped up and then distributed by pipes, to prevent contamination by handling. In the Ma-ubin jail the "meat-safe arrangement" to protect the prisoners from mosquitoes rendered the atmosphere of the wards very stuffy. The arrangement should be abandoned, and more trust put in quinine. There was a marked improvement in the health of the Moulmein jail. On the other hand, the Rangoon jail was considered to be showing signs of unhealthiness. For the first time in ten years, cholera did not make its appearance in any of the jails.* As a rule, cases of tubercle of the lungs, dysentery, and pneumonia were isolated. Separate "tubercle" wards exist in ten jails, and the question of the desirability of separate tubercle jails is being considered. The practice of producing abscess by the use of a poisoned seton was detected in the Monywa jail. The reduction of dysentery in the Moulmein jail was attributed to the facts that no water is now drunk in that jail unless it is first boiled, and that the water of the distrusted workyard wells has been rendered unpalatable by treating it with coal-tar. The scurvy admission-rate of Burma, though lowered, continued high, and was surpassed by that of Bombay only.

Assam.—The general health in the province of Assam was "extremely good." The sick ratios of the prisoners were also low, but an outbreak of "beri-beri"† in the Gauhati jail caused some increase of the death-rate. Special precautions were taken in the case of prisoners suffering from tubercle of the lungs. A committee was appointed to inquire into the causes of the unhealthiness of the subsidiary jail at Kohima. Among administrations, Assam had the highest death-rate from ague, and from anæmia and debility, and a high death-rate from dysentery; but a low death-rate from tubercle of the lungs. There was only one case of cholera. It occurred at Silchar, in the person of a man who had just travelled from Aijal.

Bengal.—The health of the general population of the Bengal Province was bad, but that of the prisoners was, on the whole, somewhat improved, and the death-rate lower than in preceding years. There was, as usual, a high death-rate from dysentery, but it was not the highest. The jail population increased and overcrowding consequently occurred in some of the jails. In most jails the question of water supply has been satisfactorily solved. There are Pasteur filters in eight jails, but on the whole they have not given satisfaction. With regard to the eight jails with the highest death-rates, the causes most frequently mentioned were, in order, poor health of prisoners on admission, overcrowding, defective water supply, dampness of a barrack. The Barisal jail was visited by an outbreak of epidemic dropsy. There occurred 12 cases of cholera distributed over 10 jails, and two cases also occurred in subsidiary jails. The disease was usually prevailing in the neigbourhood of the jail; and most of the prisoners affected were men under trial, or recently admitted into jail, or into the quarantine wards of the jail.

---

* There were two cases of "choleraic diarrhœa." † Returned as "multiple neuritis."

Where two cases occurred, no connection was discovered between them. At Monghyr a paid warder, who was supposed to have drunk infected milk, was first attacked. Every jail patient and his contacts were isolated, and, where necessary, a barrack was evacuated and disinfected. No less than 20 jails were without a death from dysentery, but malaria was more prevalent and severe. The Inspector-General believes that the statistical increase in tubercle of the lungs is the result of greater care in the correct registration of disease, and of the recognition that it is a common affection of the free population and of prisoners at the time of admission to jail. In most jails cases were isolated, and treated, as far as possible, in the open air ; while care was taken to provide spittoons, and to disinfect clothes and bedding used by phthisical patients. The Inspector-General notes in this connection that the floor space allowed per prisoner in wards does not err on the side of liberality, being less than that considered necessary for the native soldier ; and that for this reason a full ward is not very far removed from being an overcrowded one. In speaking of the Rangpur jail, an unhealthy one, he remarks that " in wards with ten rows of prisoners the floor space should be much more than it is." But there ought never to be ten rows of prisoners in a barrack ; no modern ward should contain more than two rows. The four and ten row barracks which exist in the Andamans and Bengal are a sanitary mistake, and are no doubt responsible for much avoidable sickness.

United Provinces.—The death-rate among the general population of the United Provinces was higher than in 1901, although not far removed from the average, and the prisoners had an unusually low death-rate. There was decided improvement in the health of five formerly unhealthy district jails, ascribed in the case of Moradabad partly to reforms in the water supply and in site ventilation. Among the causes mentioned for high death-rates in individual jails the most frequent are the poor health of prisoners on admission into jail and defective water supply. The site ventilation of several jails was improved by lowering internal walls and removing unnecessary walls and buildings. Pumps were provided for the wells, and other measures taken to improve the water supply and prevent pollution during distribution, in the Fatehgarh Central Prison and in eight district jails ; and the two Benares jails are being connected with the municipal waterworks. On the whole, the accommodation was more than sufficient for the daily average number of prisoners. Night latrines are being provided gradually for all barracks. The isolation of cases of tubercle was believed to have already produced good results in the Agra Central Prison. The isolation of dysentery patients and the disinfection and incineration of their evacuations were more carefully attended to than formerly. Plague occurred in three jails, and cerebrospinal fever in four. In the Benares Central Prison cholera caused 12 admissions and six deaths. The epidemic was soon checked by movement into camp. How the jail became infected is not known ; but the disease prevailed in the surrounding villages, and the medical officer mentions as a possible source that a tank outside the jail communicates with one inside, and that the first man attacked, as well as two others, were on duty near the latter tank. A sweeper, who removed the cholera excreta was among those attacked. In the infirm gang of the Ghazipur jail three cases and two deaths were recorded, and in another barrack a fatal case. The origin could not be traced, but there were cases in the city and neighbourhood at the time. The disinfectant measures adopted by the medical officer for the barracks had special reference to the destruction of flies.

Punjab.—The increased mortality among the general population of the Punjab was due to plague, there having been hardly any cholera, less fever, and the same proportion of bowel complaints. Though the disease extended so widely in the Punjab, only three deaths from plague occurred in jails. Cerebrospinal fever, on the other hand, was more frequently imported into jails from outside. The general health of the prisoners was considerably better than in the preceding year ; but the constantly sick and death-rates do not compare favourably with those of the quinquennium. As compared with 1901 there was increased mortality from small-pox, remittent fever, tubercle of the lungs, pneumonia, other respiratory diseases, and diarrhœa ; but a considerable decrease in dysentery and debility. Overcrowding, when it occurred, was met by transfer or by the use of tents. Improvement of the lateral ventilation of cells and barracks has been taken in hand, and is well advanced. Various improvements were also carried out or arranged for in the water supply of jails. High mortality in individual jails was in three cases due to cerebrospinal fever. Quinine prophylaxis was carried out in all jails, but not always with sufficient system or earnestness. A beginning has been made in the provision of special tubercle wards, and further projects are under consideration ; and much is expected from the improvement in lateral ventilation. There was no cholera in the Punjab jails.

North-West Frontier Province.—As regards the health of the inhabitants of the North-West Frontier Province the year was a favourable one ; for, though there was more fever and small-pox, there was no cholera, and very little plague. The jail statistics were less favourable than in the previous year, there being increased mortality from tubercle of the lungs, pneumonia, dysentery, and diarrhœa. The Inspector-General does not consider the number of tubercle cases sufficient to warrant the cost of providing special wards. The increase of dysentery at Peshawar was ascribed to high winds bringing dust into the food.

Bombay.—The health statistics of the prisoners of the Bombay Presidency showed much improvement, while the total mortality ratio of the general population was raised by the ravages of plague. Overcrowding occurred in nine out of the 15 prisons, and was treated by transfer, and by the use of tents, temporary sheds, worksheds, &c. The use of worksheds for the purpose is an undesirable expedient. Cerebrospinal fever broke out in the Ahmedabad Central Prison, relapsing fever in the Deccan Gang, and 24 cases of plague were distributed over six prisons. In the Sind Gang the proportion of pneumonia deaths was, as usual, high ; and new barracks with improved ventilation have been built. Many of the men who developed pneumonia in the Hyderabad Central Prison had suffered previously from scurvy. The only case recorded as cholera occurred in the Thana Special Prison. The attack began with indigestion, and there was no cholera in the town and district at the time. Prophylactic measures in regard to diet and clothing were adopted, among them the issue of potatoes in lieu of green vegetables. The description of the prophylactic use of quinine in the Yerrowda Central Prison shows that the dose was too small and the interval between doses too long.

Berar.—In Berar, there was less bowel complaint, little cholera, and the general mortality, though higher than in 1901, was not high as compared with former years. The general health of the prisoners was satisfactory. The improvement at Akola was ascribed to diminution in the number of prisoners. The medical superintendent at Amraoti dreads the cost of the extensive use of quinine as a prophylactic ; but there is good evidence to show that the least wasteful method is to repeat doses of not less than 15 grains at suitable intervals for a period of about three months. In the end less quinine is used than when smaller doses are given unsystematically, and the general hospital expenses are lowered. Though there was plague in the station and district of Buldana, the jail escaped. All newly admitted men were kept under observation and in segregation for 10 days, all the prisoners and the establishment were inoculated, and the mouths and outlets of drains were so fixed as to prevent the ingress of rats. There was no cholera.

Central Provinces.—In the Central Provinces the year was considered to be a healthy one, there being little cholera, and diminished bowel disease, though the general mortality was somewhat increased. Among the prisoners, sickness was greater than in the previous year, but the mortality was nearly 3 per 1,000 less. The apparent increase in sickness seems to have been due, partly, if not wholly, not so much to increase of disease as to greater liberality in the admission of sick men to hospital. There does not seem to have been any serious overcrowding of the jails, but timely transfer might have made it even less. The construction of tubercle isolation wards is under consideration. Under the orders of the Government of India a special investigation was made into the sanitary conditions of the Jubbulpore Central Prison, and the circumstances which had conduced to the high mortality of 1901. As a result, structural improvements were sanctioned, a complete change was made in the diet, and prisoners were more freely admitted to the infirm gang. In the jails of the Central Provinces mortality from dysentery was still further reduced ; and there was no cholera.

Madras.—As cholera, fevers, and bowel complaints were less prevalent, the mortality of the population of the Madras Presidency diminished. For the prisoners, too, it was "an exceptionally favourable year," the general ratios of sickness and mortality being diminished, as well as the death-rates from cholera, tubercle of the lungs, pneumonia, and dysentery. In the case of those jails where mortality was high, the cause was stated to have been the poor health of the prisoners on admission. Cholera occurred in the Palamcottah jail only,* and there appeared to be no connection between the three cases. The disease was prevalent in the town and district at the time. The patients were removed,

* There was one case of "choleraic diarrhœa" at Madura.

their contacts were isolated, and the cells were thorough disinfected. Notwithstanding the prevalence of plague in the vicinity of several jails, only one prisoner was attacked. In the malarious Rajamundry jail, quinine prophylaxis was combined with the attempt to destroy the larvæ of anopheles mosquitoes in the vicinity of the jail. But the principle adopted by the medical officer of treating "trivial ephemeral cases" by detention and not by admission to hospital is bad, and has been condemned by authority. Tuberculous patients are treated separately, measures are taken for the thorough disinfection and destruction of their excreta, the open air treatment is as far as possible enforced, and plans are being considered for the provision of special wards.

Coorg, Rajputana, Baluchistan.—The health statistics of the Mercara jail showed considerable improvement, the mortality being less than a quarter of that of 1901. At Ajmer and at Quetta, though there was an increase of sickness, there was a considerable reduction in mortality. At Quetta, the ratios, both of sickness and mortality, compare very unfavourably with those of the quinquennium; the average numbers of prisoners in this jail is, however, only between 60 and 70.

The General Population.

Births in India.—In 1902 the total number of births recorded among the populations under registration in the British Provinces of India was 8,791,214, a number little short of the aggregate populations of Scotland and Ireland. The birth-rate in 1902 was 39·38 per 1,000, as compared with 34·60 in 1901. In every province except Lower Burma the birth-rate in 1902 was higher than in the preceding year; in most provinces the increase was considerable, and in two, Berar and Ajmer-Merwara, enormous. In every province except three the number of recorded births exceeded the deaths, the excess ranging from 24·1 per 1,000 of population in Berar and 22·46 in the Central Provinces, to 5·20 in Assam and 3·22 in Ajmer-Merwara. In the Punjab, where the death-rate from plague alone was 8·52 per 1,000, the death-rate was 0·3 per 1,000 higher than the birth-rate, and in Bombay, where the plague death-rate was 10 per 1,000, the death-rate exceeded the birth-rate by 4·88 per 1,000. In the small province of Coorg the death-rate was 3·14 higher than the birth-rate, not because deaths were excessively numerous but because the number of births recorded was small.

The percentages of male to female births ranged from 100·77 in Coorg and 104·1 in Madras, to 121·9 in the North-West Frontier Province and 126·84 in Sind, the percentage in each province being fairly characteristic of the province; but it is noteworthy that in a year of high birth-rates in every province except Sind and the North-West Frontier Province, in the latter of which the percentage was the same as the mean of the ten years 1891–1900, the percentage excess of males was below the average.

Deaths in India.—The number of deaths recorded was 7,112,336, a number nearly equal to the populations of Sweden and Norway. The death-rate was 31·49 per 1,000, as compared with 29·46 in 1901. In all provinces except Madras, Burma, Coorg, and Ajmer-Merwara, the death-rates in 1902 were higher than in the preceding year, and in every province except Assam, where the towns are merely large villages, the urban were higher than the rural death rates.

The smallest number of deaths recorded in any one month was 468,898 in July, in which month the minima were recorded in the United Provinces, the Punjab, the North-West Frontier Province, the Central Provinces, and Ajmer-Merwara; while the largest number was 755,824, recorded in December, the month in which the maxima were recorded in Bengal and Bombay.

In the United Provinces, the Punjab, the North-West Frontier Province, Coorg, Bombay, and Ajmer-Merwara, the death-rates of females were higher than the death-rates of males; but only in the Punjab was the excess of mortality among females considerable.

The death-rates in the various provinces by ages show that infantile mortality is in some cases exceedingly large. This is due to the fact that the ratio is calculated upon the census population, and it is obvious if, at the time of the census, the population of infants in any province was low, a year in which the birth-rate is high will be marked by a high ratio of deaths with reference to the census population. Thus,

to take an extreme instance, in 1900, the year before the census was taken, the number of births recorded in Berar was 89,302, while in 1902 the number was 154,954; in 1902 the death-rate of infants, calculated on the census figure, was 620·1 per 1,000 among males and 523·3 among females; whereas the corresponding figures, calculated upon the numbers born during the year, were 203·8 and 182·9.

* Not available. † Statistics for 13 towns. ‡ Statistics of births for 13 towns only.

In the following paragraphs will be found the principal details of registration in the different provinces.

Bengal.—In 1902 the number of births registered in the 720 registering circles in Bengal was 2,987,800, or 116,994 more than in the previous year, and the birth-rate was 40·14 per 1,000, as compared with 38·57, and a quinquennial average of 37·19. In 26 of the 46 districts the birth-rate was over 40 per 1,000, the highest rates being 53·10 in Noakhali, 49·36 in Dinajpur, and 47·28 in Malda; in four districts the birth-rates were below 31 per 1,000—Midnapore 30·84, Pabna 30·16, Hooghly 30·07, and Calcutta 14·29. Calcutta is, of course, an urban district, but the birth-rate is little more than half the average of the other Bengal towns—28·11. Including Calcutta, the birth-rate in the towns of Bengal was 24·95 per 1,000, against 40·93 in rural areas. In certain of the smaller towns, however, very high birth-rates were recorded, notably in Jamalpur 74·52, Tikari 59·34, Sahibganj 57·81, Monghyr 55·85, and Revelganj 50·79. The average percentage of male to female births was 105, ranging from 102 in six districts to 109 in Howrah and Hooghly, 110 in Calcutta, 111 in Pabna, and 112 in Darjeeling, all districts in which the recorded birth-rates were very low.

The number of deaths recorded in 1902 was 2,488,428, or 178,004 in excess of the total of 1901. The death-rate was 33·43 per 1,000, as compared with 31·04 in 1901, and

30·53 the average of the previous five years. By far the highest district death-rate was 50·09 registered in Nadia; this was followed by rates of 43·35 and 42·54 in Faridpur and Jessore respectively. The three lowest district rates were recorded in Ranchi 25·22, Tippera 23·15, and Sonthal Parganas 21·02. The average death-rate in the towns was 35·98, or 2·68 per 1,000 higher than the average in rural areas. In 18 towns, including Hooghly and Chinsura (56·05) and Pabna (55·67), the death-rates were over 50 per 1,000, the highest rates being 105·72 recorded in Barh, a town of 12,000 inhabitants in the Patna district, 65·23 in Revelganj, a small town in Saran, and 64·13 in Chapra, a town of about 46,000 inhabitants, also in Saran. In most of the towns where the death-rate was excessive plague was present.

The death-rates among infants were 301·80 and 254·05 per 1,000 living of males and females respectively; among children between one year and five years of age the rates were 50·67 among males and 44·28 among females. At all age periods the male death-rates were the higher, the average death-rates being 35·36 and 31·50 among males and females respectively.

Among the various sects the lowest death-rate was registered among Christians (19·36), followed by 21·14 among Buddhists and 28·27 among other classes. Hindus and Muhammadans died at the rates of 33·40 and 34·0 respectively.

The number of European seamen who arrived in the Port of Calcutta was 20,146, the daily average population in the Port being 1,154. The number of deaths reported was 23, including 13 from cholera, equal to a total death-rate of 19·93, as compared with 16·52 in 1901. The estimated floating native population of the Port was 25,630, among whom 138 deaths, including 63 from cholera, were reported, equal to a total death-rate of 5·37, against 5·34 in 1901.

Assam.—The number of births registered in Assam in 1902 was 180,475, as compared with 179,289 in the preceding year, and the birth-rate was 34·21, against 33·98 in 1901, and the quinquennial mean of 32·21. The highest district birth-rate was, as usual, recorded in Goalpara (45·23 per 1,000), and following this were birth-rates of 37·15 and 35·58 in Sylhet and Cachar respectively; the lowest rate was 24·46 in Sibsagar. The percentage of male to female births ranged from 112·24 in Nowgong to 101·68 in Cachar, the mean being 106·66.

The recorded deaths numbered 153,070, or 6,131 more than in 1901, and the death-rate was 29·01, against 27·85 in the previous year, and 33·90 the mean of the previous five years. In the districts the death-rates ranged from 35·72 in Darrang to 18·14 in Sibsagar. In the towns the mean death-rate was 28·52, against 29·03 in rural areas; and in the towns the recorded rates varied much more than in rural areas, from 46·73 in North Lakhimpur to 15·86 in Sunamganj. It may be noted that the most populous of the 19 towns in Assam contains only 13,893 inhabitants, and only three others contain over 10,000. Among Christians the death-rate was 14·13, among Hindus 23·77, among Muhammadans 34·93, and among other classes 44·79. Male infants died at the rate of 198·53 per 1,000 living at the time of the census, and female infants at the rate of 179·61. Children over one year of age and under five died at the rates of 35·75 and 35·24 per 1,000 among males and females respectively. At all age periods, save 15–20 and 20–30, the male death-rates were the higher, the means being 29·46 among males and 28·54 among females.

Assam tea gardens.—The mean annual strength of the labour force in Assam in the twelve months ending the 30th June, 1903, was 644,045, of which total 60·23 per cent. were employed in the Assam Valley and 39·77 in the Surma Valley. The birth-rate was 30·8 per 1,000 of the total number, and 98·6 per 1,000 adult females, a slightly lower figure than the birth-rate calculated on the number of births registered per 1,000 adult females in the general population.

The total number of deaths among the coolies was 16,376, including 1,024 from cholera, 1,571 from diarrhœa, 2,516 from dysentery, 2,612 from malarial fever, 2,150 from anchylostomiasis, and 1,928 from respiratory diseases.

The number of gardens, which was 812 at the beginning of the year, fell to 788 before its close, and among them 11 only were classed as unhealthy, that is, showed a a death-rate of 70 per 1,000 or over.

The number of deaths among all classes of immigrants during their transit between the port of embarkation and their destination in the Assam Valley was 57, including 42 from cholera. Among the immigrants to the Surma Valley there was no death on the railway, and only one among the coolies who travelled by steamer.

United Provinces of Agra and Oudh.—The number of births recorded in the United Provinces reached a total of 2,186,201, or 214,070 more than in 1901, and the birth-rate was 45·84 per 1,000, against 41·35 in the previous year, and 39·65 the mean of the previous five years. Among the districts the three highest birth-rates were recorded in Hamirpur, 56·74 ; Shahjahanpur, 55·84 ; Pilibhit, 54·97 ; and the three lowest in Ballia, 37·28 ; Naini Tal, 35·11, and Dehra Dun, 30·04. The mean birth-rate of the towns was 43·35, ranging from 63·03 per 1,000 in Ujhani, to 23·79 in Mirzapur-Bindachal, 21·21 in Naini Tal, and 14·0 in Mussoorie. The percentage of males born to females born was 117·64 in Dehra Dun, and in the other districts it varied between 110·70 in Muttra and 101·98 in Garhwal, the average for the province being 107·25.

The deaths registered during 1902 numbered 1,552,046, as compared with 1,445,035 in the preceding year, and the death-rate was 32·54 per 1,000, against 30·30 in 1901, and the quinquennial mean of 32·48. The highest district death-rates were 49·50 in Cawnpore, 43·78 in Naini Tal, and 43·06 in Meerut, while the lowest were 23·80, 24·33, and 24·60 in Azamgarh, Gorakhpur, and Almora respectively. In rural areas the average death-rate was 31·46, while in the towns the average was 46·69, ranging from 104·94 in Cawnpore and 78·60 in Jaunpore, to 23·32 in Balrampur and 18·29 in Basti. The lowest death-rate in the year was recorded in July, the highest death-rates in October and November.

Christians are reported to have died at the rate of 10·36, and "other classes" at the rate of 13·92. The Muhammadan death-rate was 33·27, and the Hindu 32·55.

The death-rate of infants was very high, 374·97 and 348·53 among males and females respectively. Boys and girls over one and under five died at nearly the same rates, 59·01 and 59·49 respectively. In the age periods, 10–15, 15–20, 20–30, the female rates were higher than the male rates, the average death-rates of the sexes being almost identical—32·54 and 32·55.

Punjab.—In 1902 there were 880,477 births registered in the Punjab, against 712,533 in the previous year, and the birth-rate was 43·8 per 1,000, as compared with 35·4 in 1901, and the quinquennial mean of 40·0. In ten of the districts the birth-rate was over 45 per 1,000, the highest rate being 54·4 in Sialkot, 52·1 in Gujrat, and 49·0 in Gurdaspur ; and in only two districts were the rates below 35, namely, Dera Ghazi Khan (34·9) and Simla (19·1). The percentage of male and female births was 110·4 ; in Dera Ghazi Khan the percentage was 120·2 ; in the other districts it varied between 115·2 in Simla, 115·0 in Mianwali, and 105·5 in Ludhiana.

The number of deaths recorded was 886,973, or 160,362 more than in 1901, and the death-rate rose from 36·1 per 1,000 in the preceding year to 44·1, which is 10·4 per 1,000 higher than the quinquennial mean. In some of the plague-stricken districts the rates were very high, notably in Ludhiana 103·9, Sialkot 66·7, Umballa 66·6, Jullundur 54·8, and Gurdaspur 51·0 ; in others from which plague was absent, the death-rates were low, *e.g.*, Dera Ghazi Khan 24·2, Montgomery 23·4, and Simla 21·3. In rural areas the average death-rate was 43·53 per 1,000, against 49·39 in the towns. Among the latter, death-rates of over 100 per 1,000 were recorded in six, namely, Khanna 177·44, Jagraon 152·99, Raikot 136·81, and Machiwara 132·61, all in Ludhiana, Jamke in Sialkot 142·79, and Rupar in Umballa 111·61. In all cases the excess death-rate was due to plague. In a few towns the recorded death-rates were very low, the lowest being 18·93 in Kot Mithan, 17·49 in Leiah, and 15·75 in Montgomery. The monthly death-rates were at their highest in March 5·64, and April 5·52, and at their lowest in June 2·47, July 2·07, August 2·39, and September 2·56.

Among the sects by far the lowest death-rate was recorded among Christians, 23·74 per 1,000, and the highest among "other classes," 50·29. Muhammadans and Hindus died at the rates of 41·88 and 46·75, respectively.

Male infants died at the rate of 316·44 per 1,000 living, and females at the rate of 320·76. Children over one year and under five years of age died at the rates of 62·16 and 65·93 among males and females, respectively. In all age periods the female death-rates were the higher, the average death-rate of males being 41·1, and of females 47·6 per 1,000.

North-West Frontier Province.—The number of registered births in the North-West Frontier Province was 66,904, or 6,491 more than in 1901, and the birth-rate was 33·6 per 1000, as compared with 29·5 in the previous year, and an average of 30·7 recorded in the previous five years in the districts of which the province is made up. The highest district rate was 37·7 in Dera Ismail Khan, and the lowest 31·8 recorded in two districts, Hazara and Peshawar. The average percentage of male to female births was 121·9.

There were 48,624 deaths registered against 39,208 in 1901, and the death-rate was 24·4 per 1,000 as compared with 19·2 in the previous year, and a quinquennial mean of 23·7. Although the death-rates in the districts varied much, from 33·3 in Kohat to 20·7 in Hazara, no rate was very high, and there were only four deaths from plague during the year. The rural death-rate was 24·14 against 27·57 in the towns, among which the rates ranged from 35·18 in Dera Ismail Khan, to 17·97 in Abbottabad.

Muhammadans and Hindus died at the rates of 24·92 and 21·67, respectively ; and the death-rates of Christians and other classes are given as 4·14 and 2·51.

Male infants died at the rate of 180·22 and female infants at the rate of 145·00 per 1,000 living, respectively. Children between the ages of one year and five years died at the rates of 43·59 and 42·87 per 1,000, respectively. The female death-rate was higher than the male in every age period except 0–1, 1–5, and 50–60.

Central Provinces.—The number of births registered in the Central Provinces, including zamindaries, in 1902 was 471,774, or 191,776 more than in 1901, and the birth-rate reached the high figure of 48·29 per 1,000 as compared with 28·83 in the preceding year. The highest birth-rate, 76·34 per 1,000, was reported from the Bilaspur zamindaries and the lowest 38·56 from the British territory in the same district, a contrast with which redistribution of the population after the famine, during which the census was taken, has probably much to do. In the other districts the rates ranged from 59·89 per 1,000 in Wardha and 58·51 in Nimar, to 40·04 in Raipur and 40·14 in Sambalpur. The percentages of male to female births varied from 107·77 in Nagpur, to 100·68 in Murwara, the mean percentage being 104·78.

The deaths numbered 252,279 against 227,853 in 1901, and the death-rate was 25·82 against 23·46. In no district was the death-rate excessive, and in some the rates were very low, the extremes being 38·95 in Burhanpur (plague 7·95) and 18·99 in Bilaspur (*khalsa*). The rural death-rate was 25·23 against 32·42 in the towns, in a few of which plague occurred, notably, Burhanpur, total death-rate 55·67 (plague death-rate 19·37), and Jubbulpore, total death-rate 44·79, including 2·87 from plague. In the other towns the rates ranged from 42·13 in Kalmeshwar, in Nagpur, and 12·52 in Mandla.

The death-rate of Muhammadans was 32·18 per 1,000, of Hindus 22·70, and of " other classes" 43·21.

The death-rate of infants, calculated upon the census population of infants, was 492·91 among males and 431·12 among females, but calculated on the numbers of births registered during the year the rates were 224·14 among males and 201·95 among females. Boys between the ages of one year and five died at the rate of 32·84, and girls at the rate of 29·23 per 1,000. At all periods, save 15–20, the male death-rates were the higher the average death-rate among males being 27·55, and among females 24·15.

Berar.—A combination of favouring circumstances resulted in the birth-rate being the highest ever recorded in Berar ; 154,954 births were registered against 83,762 in 1901, and the birth-rate was 56·9 per 1,000 against 30·8 in the previous year, and 38·2 the mean of the previous five years. In every district the rates were very high, ranging from 62·7 in Buldana to 53·2 in Amraoti. The rural birth-rate was 58·3 per 1,000 against 49·1 in the towns. The mean percentage of male to female births was 104·7, varying between 108·1 in Ellichpur, and 102·3 in Wun.

The recorded deaths numbered 89,153, or 14,073 more than in 1901, and the death-rate was 32·8 per 1,000, as compared with 27·6 in the previous year, and the quinquennial mean of 46·7. The district death-rates varied considerably, Buldana 41·0, and Basim 28·7, furnishing the extremes. In rural areas the death-rate was 32·0 per 1000 against 36·6 the average in the towns. In a few of the latter the death-rates were very high, Khamgaon in Akola 99·3 per 1,000, of which 64·3 per 1,000 was due to plague, Shegoon in the same district, 53.6, of which 22·9 was due to plague, and Chikhli in Buldana 48·2, of which 11·5 was due to plague, being the most conspicuous. In only five towns were rates below 25 per 1,000 registered, namely, Ner Pinglai 24·8, Mangrul Dastagir 24·7, Wun 24·4, Pusad 24·0, and Talegaon 23·9.

Among Muhammadans and Hindus the death-rates were, respectively, 32·2 and 32·7, and among Christians and other classes 14·6 and 37·0.

Owing to the small population of infants at the time of the census and the enormous birth-rate of the year, the infantile death-rates computed upon the census figures were very high, 620·1 and 523·3 for male and female infants, respectively ; but computed upon the number of births recorded during the year those death-rates were only 203·8 and 182·9. The death-rate of boys over one year of age and under five was 62·5, and of girls

56·2. In the age periods, 10–15, 15–20, 20–30, and 30–40, the female death-rates were the higher, the average for the sexes being 33·5 and 32·1 among males and females respectively.

Madras.—In 1902 the number of births registered in Madras was 1,023,146, as compared with 935,749 in the preceding year. In 1902 the birth-rate was 28·2 per 1,000, against 25·1 in the previous year, and 28·9, the average of the previous five years. In the districts the birth-rates ranged from 34·9 in Madras town district and 33·6 in Tinnevelly, to 22·8 in Ganjam and 22·4 in North Arcot. In rural areas the average birth-rate was 28·1, or 1·1 per 1,000 less than in the towns. The mean percentage of male to female births was 104·1, ranging from 110·0 in the Nilgiris, 108·6 in Ganjam, and 105·5 in North Arcot and Tanjore, to 100·0 in Nellore. In the towns the mean percentage was 105·7.

The recorded deaths numbered 732,437, or 63,703 fewer than in 1901, and the birth-rate was 20·2 per 1,000, as compared with 21·3 in the previous year, and 22·2 the mean of the previous five years. By far the highest death-rate was registered in the Madras town district, where the people died at the rate of 42·4 per 1,000. After Madras came Bellary, with a death-rate of 32·6. Among the other districts death-rates varied between 26·3 in the Nilgiris, and 15·1 in Vizagapatam and 11·9 in Ganjam. In rural areas the mean death-rate was 19·3, or 8·9 less than the mean rate in the towns, which was 28·2. In Vaniyambadi, a town of about 12,000 inhabitants, in the Salem district, the death-rate was 128·9, including rates of 80·1 from plague, 3·7 from cholera, and 2·7 from small-pox. In Adoni, in the Bellary district, the death-rate was 56·5, including 28·9 from plague and 6·3 from cholera. In Hospet, also in Bellary, the death-rate was 48·9, including 34·1 from plague and 1·0 from cholera. In Bellary the death-rate was 48·0, including 24·0 from plague and 1·2 from cholera. In the remaining towns the rates ranged from 42·0 in Yemmiganuru to 5·1 in Vempalli, a town of about 10,800 inhabitants in Cuddapah, and 3·4 in Nellikuppam, in South Arcot.

While Muhammadans died at the rate of 21·2 per 1,000, Hindus at the rate of 20·4, and Christians at the rate of 18·1, the registered death-rate among 1,559 included among "other classes" was only 3·9.

The death-rate among male infants was 169·0 per 1,000 living at the time of the census, against 140·9 per 1,000 among female infants. Boys and girls over one year and under five years of age died at the rates of 28·1 and 26·5 respectively. At the age period 10–15, the death-rates of the sexes were equal; at all age periods, except 15–20 and 20–30, the male death-rates were the higher, the mean rates being 20·8 among males and 19·5 among females.

Coorg.—In the small province of Coorg, in 1902, there were registered 4,319 births, equal to a birth-rate of 23·91 per 1,000, against 18·83 in 1901 and a quinquennial mean of 20·67. In the districts the rate ranged from 31·20 in Padinalknad to 17·76 in Yedinalknad. The percentage of males born to females was 100·98.

The number of deaths recorded was 4,887, and the death-rate fell from the quinquennial mean of 35·25 per 1,000 and 36·49 in 1901 to 27·06 in 1902. The highest district death-rate was 29·80 in Nanjarajapatna Taluk, and the lowest 24·16 in Yedinalknad, the urban rate being 36·92 against 26·15 in the country.

The death-rate of male infants was 167·99 per 1,000, and of females 151·53. At the age periods, 10–15, 15–20, 20–30, 30–40, and 60 and over, the female death-rates were the higher, and the mean death-rates of the sexes were 26·87 among males and 27·31 among females.

Bombay.—In Bombay, in 1901 the number of births recorded was only 465,647, equal to a birth-rate of 25·19 per 1,000; but in 1902 there was a great increase, the number of births rising to 631,393 and the birth-rate to 34·16, which is 3·59 per 1,000 in excess of the quinquennial mean.

Khandesh heads the list of districts with the high birth-rate of 52·93 per 1,000, and this, it may be noted, in spite of the prevalence of plague, which caused a death-rate of 17·58 per 1,000. The next highest birth-rates were 44·67 and 44·46, in Ahmednagar and Panch Mahals, respectively. As usual, the lowest birth-rates were recorded in the Sind districts, Thar and Parkar, with a birth-rate of 16·54, being the lowest. In the country the mean birth-rate was 35·23, against 27·09 in the towns. The mean percentage of male to female births in the whole presidency was 107·80; but in Bombay proper the percentages varied between 109·40 in Ahmedabad and 100·27 in Bijapur; whereas in Sind the percentages ranged from 136·64 in Hyderabad to 116·78 in Karachi.

The number of deaths recorded in 1902 was 721,462, or 35,328 more than in the previous year, and the death-rate was 39·04 per 1,000, against 37·12 in 1901 and a quinquennial mean of 42·40. Excluding the town district of Bombay City, in which the death-rate was 63·13, the highest death-rates were 58·29 and 58·07, recorded respectively in Kaira and Dharwar, and the lowest were 20·22 in Sukkur, 18·77 in Ratnagiri, and 17·66 in Upper Sind Frontier. In rural areas the mean death-rate was 35·85, but in the towns, many of which suffered terribly from plague, the mean was 60·22, ranging in individual towns from 185·22 in Yeola, in Nasik, and 153·14 in Gokak, in Belgaum, to 15·04 in Vengurla, in Ratnagiri, 14·34 in Ahmedabad cantonment, and 10·61 in Ahmednagar cantonment.

Hindus died at the rate of 41·68, Muhammadans and Parsis at the rates of 30·04 and 27·30 respectively, and Christians and "other classes" at the rates of 25·31 and 23·98.

The death-rates of infants, calculated upon the census population, were 318·47 and 286·11 per 1,000, and of boys and girls over one year and under five years of age, 44·79 and 43·90 respectively. Although at all age periods except 5–10, 10–15, and 15–20 the male death-rates were the higher, the mean death-rate of males was 38·77 per 1,000 against 39·32 per 1,000 among females.

Lower Burma.—The number of births recorded in Lower Burma in 1902 was 175,106, or 2,759 less than in 1901, the slight decrease being probably due to a relaxation of energy in the supervision of the inspection of registers. The birth-rate was 31·57, or 0·5 per 1,000 less than in 1901, and about 3 per 1,000 less than the quinquennial mean, which, however, is calculated in respect of four years on a population about 21 per cent. smaller than that on which the rates for 1902 are calculated. Among the district rates over 40 per 1,000 were registered in Tharrawaddy (40·80) and Sandoway (40·09), the remainder ranging from 38·53 in Henzada to 23·04 in Toungoo and 14·11 in the Rangoon Town district. The rural birth-rate was 32·52, as compared with a mean of 24·46 in the towns, in which, with two exceptions, the birth-rates varied between 42·91 in Allanmyo and 17·32 in Akyab. The exceptions were the little town of Zigon, in which the highest birth-rate (89·73) of 1902 was registered and the town of Rangoon, in which again the lowest birth-rate is recorded. The percentage of males to female births was 107, but the variation in the districts was considerable, from 111 in Pegu to 103 in Henzada, and 102 in Rangoon Town district.

The recorded deaths aggregated 117,386 against 120,565 in 1901, and the death-rate was 21·16 per 1,000 against 21·74 in 1901, and a quinquennial average of 25·79. By far the highest district death-rate was 33·57 registered in Rangoon town, and this is followed by a rate of 26·13 in Sandoway; in the remaining districts the death-rates varied from 23·86 in Pegu to 15·21 in Mergui. The rural death-rate was 19·97, nearly 10 per 1,000 lower than the mean urban rate which was 29·93, ranging from 54·51 in Zigon and 43·86 in Kyaiklat to 20·70 in Tavoy and 10·93 in Mergui.

Christians and Muhammadans died at the rates of 12·13 and 16·40 per 1000; Buddhists and "others" at the rates of 21·59 and 19·42; and Hindus died at the rate of 24·16.

Male infants died at the rate of 307·47 per 1,000 living at the time of the census, and females at the rate of 221·89. Boys and girls between the ages of one year and five years died at the rates of 26·13 and 22·46, respectively. At all age periods the male death-rates were the higher, the mean death-rate of males being 22·37 and of females 19·81.

Upper Burma.—In 13 towns in Upper Burma both births and deaths are registered, and in the districts, of which, however, the population figures are not available, deaths are registered.

The mean birth-rate in the towns was 38·0 per 1,000, the rates ranging from 57·01 in Kyaukse to 20·42 in Minbu; and the mean death-rate was 29·95, the same towns, Kyaukse (43·73) and Minbu (14·19), furnishing the extremes.

Ajmer-Merwara.—The number of births recorded in Ajmer-Merwara in 1901 was only 7,679, but in 1902 the number rose to 17,207, equal to a birth-rate of 36·08 per 1,000 against 16·10 in 1901, and a quinquennial mean of 28·13. The percentage of male to female births was 115·25 as compared with 119·15 in 1901 and 123·79 in 1900.

The deaths in 1901 numbered 15,798, and in contrast to the vast increase in the number of births, the number of deaths in 1902 fell to 15,672, equal to a death-rate of 32·86 as compared with 33·13 in 1901, and a quinquennial mean of 52·11. The rural death-rate was 29·88, while the mean death-rate in the towns was 40·85.

Hindus and Muhammadans died at the rate of 35·05 and 31·49 per 1,000, respectively.

Male and female infants died at the rates of 219·15 and 214·41 per 1,000 registered births. In the age periods 15-20, 20-30, and 30-40, the female death-rates were the higher, the mean death-rates of the sexes at all age periods were 32·73 among males and 33·01 among females.

History of the Chief Diseases.

Cholera.

The number of deaths from cholera recorded in British territory during 1902 was 224,136, equal to a death-rate of 1·01 per 1,000 of the total population under registration. If the deaths recorded in the native states from which returns were received be added, the total amounts to 225,885. In the previous year 271,210 deaths from cholera were recorded in British territory, giving a ratio of 1·21 per 1,000 of population, so that during the year under review a considerable reduction in the mortality from this disease occurred; and, as compared with 1900, when no less than 797,222 deaths from cholera were recorded in the British provinces alone, the decrease during 1902 was very great. Although the disease was, on the whole, more prevalent during the first half of the year than the second, the month of least prevalence during the whole year was February. From April, which was the month of maximum prevalence, a steady fall in the number of deaths recorded each month occurred until the end of October, the mortality again increasing in November and December. The disease was most prevalent during the year in Assam, Bengal, and Madras; but in all the provinces except Bengal, Assam, and the Punjab, the mortality was less than in the previous year. The North-West Frontier Province and Coorg were quite free from cholera, and the Central Provinces nearly so.

Deaths from Cholera in the different Provinces in India from 1877 *to* 1902.

‖ Excluding Zamindaries.
(a) Separated from the Punjab in 1901.

Assam.—The number of deaths attributed to cholera in Assam during 1902 was 12,658, a ratio per 1,000 of 2·40 of the last census population, and the highest ratio among the provinces for the year. In the previous year 7,468 deaths were recorded from cholera in this province, so that the increased prevalence of the disease during the year under review was considerable ; though the number of deaths and the death ratio were still considerably below the average figures for the past 16 years. The chief outbreak occurred in the Sylhet district, where there were recorded 8,804 deaths from this disease as compared with 2,805 in 1901. The Goalpara, Darrang, and Nowgong districts, which were so severely visited in 1900, were again, as in 1901, comparatively free from cholera in 1902 ; in the Nowgong district, where the death-rate in 1900 was 24·95 per 1,000, the death-rate in 1902 was only ·08 per 1,000. A severe outbreak occurred in the Sunamganj and Habiganj subdivisions in September, and lasted until the end of December. A similar outbreak had occurred in these subdivisions in 1900. Except in the Sylhet district, the rates in tea gardens were everywhere higher than the registered general rates. In the Surma valley, however, out of a labour population of 273,939 the number of deaths recorded was 467, giving a ratio of 1·70 per 1,000 as compared with a ratio of 3·86 in the remainder of the valley. In the Brahmaputra valley the rates for tea gardens and for the rest of the valley were 1·89 and 1·01 per 1,000, respectively.

The number of tea-garden cooly immigrants increased slightly as compared with the previous year, but the death-rate among them while in transit from Goalundo to the port nearest to the place of their employment fell from 2·6 per 1,000 to ·9 per 1,000, which shows, in the provincial Sanitary Commissioner's opinion, that greater precautions are taken on the steamers, and greater care exercised not to embark infected coolies. As low and lower rates have, however, been recorded even as far back as 1890 and 1893.

Bengal.—In Bengal in 1902 the total number of deaths recorded as due to cholera was 150,971, or 2·02 per 1,000 of the population, as compared with 110,753 or 1·48 per 1,000 in 1901. The disease appeared in every district during 1902, attacked 22,642 villages and assumed an epidemic form in 67 registering circles, as compared with 43 in 1901. The highest district ratios were those of Muzaffarpur, 24-Parganas, Howrah, Nadia, and Faridpur, while Ranchi and Darjeeling were the least affected of all the districts. As compared with 1901, the incidence of the disease during 1902 was higher in all but 11 districts. The highest municipality and town death ratios were 27·46 per 1,000 in Sitamarhi in the Muzaffarpur district, 16·31 in Kotrung, and 12·34 in Baidabati, both in the Hooghly district. The ratios of 27 other towns ranged from 5 to 11·67 per 1,000. The provincial Sanitary Commissioner offers no remarks on the increased prevalence of cholera during 1902. In 20 districts during the cholera outbreaks, the tanks and wells used for drinking purposes were disinfected with permanganate of potassium, and the Sanitary Commissioner remarks that though in most places no systematic record of results was kept, the measure is generally said to be attended with beneficial results. Among the European seamen of the port of Calcutta there were 13 deaths from cholera, and there were 63 among the native floating population.

United Provinces.—Although in 1902 the cholera death-rate in the United Provinces was the fourth highest among the provinces, the mortality from this disease was considerably less than in 1901. The total number of deaths from cholera recorded was 25,160, giving a ratio of ·53 per 1,000 of population, as compared with a total of 53,995 and a ratio of 1·13 during 1901. The disease caused the greatest number of deaths in May and the fewest in February. The highest district death-rates in order were those of Banda, Garhwal, Naini Tal, Basti, Fyzabad, and Allahabad, and the highest town mortalities those of Banda (14·8 per 1,000), Kashipur (11·14 per 1,000), and four other towns with ratios ranging from 5·48 to 3·08. In 57 towns no death from cholera was recorded.

Punjab.—Although cholera was slightly more prevalent in the Punjab during 1902 than during 1901, the province was, as in the previous year, almost entirely free from the disease. The total number of deaths recorded was 371, giving a ratio of ·02 per 1,000, as compared with a ratio of ·01 in 1901, and a mean mortality ratio for the previous five years of ·27. With the exception of an isolated outbreak, which occurred in December in the Kangra district, the disease was almost entirely confined to a few

districts in the Delhi division. The largest numbers of deaths were recorded in the Umballa and Gurgaon districts. The Civil Surgeon of the Kangra district gives the following account of the outbreak there :—

"There were 66 seizures with 38 deaths in the village of Sansai during the month of December, 1902. The infection was brought to the village by a sepoy returning from Burma ; after the man's death, his wife washed his clothes in the tank from which one half of the village procured their drinking water. The village is divided into two parts by a rivulet, and each half of the village has a separate spring and tank for drinking water. One half of the village had no cases of cholera, whilst the other half, the water supply of which had been polluted, developed 65 cases of cholera in seven days. The inhabitants ceased to use the infected water and the tank was disinfected with permanganate of potassium. The cases ceased immediately.

North-West Frontier Province.—No death from cholera was recorded in the North-West Frontier Province during 1902. In 1901 the total number of deaths was 117, a ratio of ·06 per 1,000 of population.

Bombay Presidency.—In the Bombay Presidency the death-rate from cholera during 1902 was between one-fourth and one-fifth that of 1901. Since 1877 there have been only two years, viz., 1880 and 1886, in which a smaller mortality from cholera was recorded than in 1902. Out of 220 rural circles 34 were affected by cholera in 1902, but in nine only was it prevalent to any extent. The highest percentages of affected villages were in the collectorates of Karachi and Hyderabad, and in the remaining 16 affected collectorates less than one per cent. of the villages were attacked by the disease. The Deputy Sanitary Commissioner, Sind Registration District, considered, after very careful enquiry, that the disease was most probably imported into that district by immigrants entering Sind viâ the Thar and Parkar district.

Berar.—Only 16 deaths from cholera were recorded in Berar during 1902, as compared with 17 in 1901 and 18,375 in 1900. The number of deaths from this cause during 1902 in Berar is the lowest since 1880, except 1898 when the province was free from the disease. The whole province was free from the disease except the village of Hingna Gawhal in the Buldana district, where a small outbreak causing 16 deaths out of 48 attacks occurred in May. The Sanitary Commissioner of the Hyderabad Assigned Districts says that it was discovered that the infection was brought by a party returning from pilgrimage to Upper India and Bengal. The speedy disappearance of the disease was said to have been aided by disinfection of the drinking water-supply with permanganate of potassium.

Central Provinces.—The Central Provinces also remained almost entirely free from cholera during 1902, only 28 deaths being recorded from this disease, as compared with 49 in the previous year. With the exception of the year 1898 the figures for 1902 are the lowest on record. Of the 28 deaths, 26 occurred at Bilaspur and one each at Marwara and Bhandara. The two latter cases were said to have been imported from Allahabad and Benares, respectively. The origin of the outbreak in Bilaspur could not be satisfactorily explained.

Madras Presidency.—In the Madras Presidency there were 29,769 deaths recorded as due to cholera during 1902, giving a ratio of ·8 per 1,000 of population, as compared with a total of 81,370 and a ratio of 2·2 per 1,000 in 1901. The districts of Tinnevelly, Tanjore and Bellary were most severely affected. The provincial Sanitary Commissioner points out that the difference of incidence of cholera in municipalities during 1902 is slightly in favour of those municipalities which adopted the so-called municipal cholera rules as a compulsory measure, and notes with satisfaction that certificated sanitary inspectors are slowly displacing in rural areas the untrained conservancy overseers. In the larger towns considerable attention has been paid to water-supplies, and some slight advance has been made in this direction in rural areas.

Coorg.—No death from cholera was recorded in this small province during 1902. There was also no cholera in Coorg during 1899 and 1900, but in 1901 the disease caused 58 deaths.

Burma.—In Lower Burma during 1902 there were recorded as due to cholera 1,844 deaths, or a ratio of ·33 per 1,000 of population as compared with 3,552, or ·64 per 1,000, from the same cause in 1901. The number of deaths during 1902 is the

lowest since 1890. The largest numbers of deaths in districts were 471 in Thôngwa, 288 in Henzada, 237 in Bassein, and 200 in Myaungmya, and the highest rates in towns were 6·05 per 1,000 in Kyaiklat, 4·37 per 1,000 in Zalun, and 4·30 per 1,000 in Yandoon. In four districts and in 15 towns no death from cholera was recorded. The total number of persons reported to have been attacked by the disease was 1,944, and the high case mortality (95 per cent.) indicates that a large number of attacks were not reported. As regards seasonal distribution, the disease was most prevalent in April, March and February, and the fewest deaths occurred in September, October and August.

In Upper Burma the total number of deaths recorded as due to cholera during 1902 was 57. Four districts and 10 out of the 13 towns returned no death from this cause, and of 9,340 villages, from only 20 were cholera deaths returned.

Anti-cholera inoculation.—In the year 1902 the total number of operations performed at the Purulia depôt in Bengal, the only place where inoculation is systematically carried out, was 3,144, as compared with 3,453 in 1901 and 13,291 in 1900. The subjects were all coolie emigrants proceeding to the tea districts of Assam and Cachar. The large decrease is mainly due to the fact that while formerly all the coolies recruited from the Central Provinces as well as from the districts of Palamau and Ranchi used to halt at Purulia where they were inoculated, they now do not break their journey at Purulia, but proceed viâ Asansol to the labour districts of Assam. Since the close of the year 1902, however, arrangements have been made to have all these coolies inoculated at Asansol. Out of 106 inoculated coolies on board the steamer plying between Goalundo and Dibrugarh, it is reported that only one man got cholera and he recovered, while out of 1,192 uninoculated coolies, 18 are said to have been attacked by it, four of the cases ending fatally.

Small-pox.

The death ratio per 1,000 of population from small-pox during 1902 rose by ·12 per 1,000 as compared with that of 1901. The total number of deaths was 115,443 as compared with a total (excluding Upper Burma) of 89,378 in 1901, and a total of 84,780 in 1900. The mortality ratio from small-pox in Assam was very much higher than in either of the two preceding years, chiefly as a result of several outbreaks in the districts of the Surma valley. The provincial Sanitary Commissioner attributes the outbreaks largely to the visits of inoculators. The disease was also very prevalent in the Hailakandi subdivision of the Cachar district where inoculation was largely practised.

Statement showing the deaths from Small-pox registered in British Provinces by Months during the year 1902.

* Excluding Chhatisgarh Zamindaris † Not available.

The prevalence of small-pox in Bengal has been increasing steadily since 1899, and during 1902 caused 19,750 more deaths than during 1901, the number of deaths from this cause during 1902 reaching the high total of 57,430. The provincial Sanitary Commissioner remarks that the present arrangement by which vaccination in outlying tracts is practically left to the unchecked supervision of the subordinate inspecting staff, is risky and defective, and proposals have been submitted to Government to remedy this state of things. In the United Provinces the death-rate during 1902 was five times as high as during 1901. In the Punjab the ratio was nearly twice as high as in 1901 and the total number of deaths 11,629 as compared with 6,154 in 1901. The provincial Sanitary Commissioner points out that in the districts in which small-pox was very prevalent during the year 1902 the number of persons successfully vaccinated per 1,000 of population was, with one or two exceptions, lower than the average for the province. It is satisfactory to observe that in the 22 towns in which vaccination is compulsory the mortality from small-pox was comparatively low, viz., ·6 per 1,000 as compared with a death-rate for all the towns of ·9 per 1,000. In the North-West Frontier Province the mortality from small-pox was slightly increased. The Civil Surgeon of Dera Ismail Khan considered that many deaths from measles were recorded as having been due to small-pox. In the Bombay Presidency the death-rate from small-pox in 1902 was less than half that in the previous year, but in Berar the death-rate was higher than in 1901. In the Central Provinces, in the Madras Presidency, and Lower Burma the mortality decreased considerably as compared with the previous year, and there was very little small-pox in the towns of Upper Burma.

Plague.

The mortality from plague in India was first shown in a separate table in this report for 1898. During that year 98,613 deaths from the disease were recorded, and in the next year the number of recorded deaths reached a total of 139,009. In 1900, however, there was a decided decrease in plague mortality, only 92,807 deaths being recorded, but in 1901 the number, viz., 283,788, far exceeded the combined totals of the two previous years. In 1902 a still further increase occurred, no less than 583,937 deaths being attributed to this disease alone, a mortality which is not less than that of cholera in a year of severe epidemic. In 1898 the month of maximum prevalence of plague was October, but for the three years from 1900 to 1902 the month of highest mortality was March, and for each of the five years except 1900, when it was July, the month of minimum prevalence was June. During 1902 all the provinces of India were more or less affected except Assam, Burma, and Coorg, where no deaths from plague were recorded, the North-West Frontier Province where only 4 deaths were recorded, and Ajmer-Merwara where only one death was recorded.

A résumé of the literature bearing upon plague has been given in this report in former years, and a few references to recent contributions will be given here, although it may be noted that there is much apparent inconsistency in the results recorded by different observers.

The bacillus.—As a result of a bacteriological and pathological examination of 2,200 rats among those killed in connection with the outbreaks of plague at Odessa, Skschivan arrives at the conclusion that there exists absolutely no difference between the bacillus of rat plague and that of human plague, the disease in rats and in men being in fact caused by one and the same bacillus. The assertion of Caldas, referred to in the last report, that the human plague bacillus is but a rat colon bacillus of high virulence, is quoted by Pfaundler as an example of the fantastic conclusions into which a want of the critical faculty in research can lead observers. True plague bacilli are not, however, always found in rats suspected to have died from plague. E. Klein isolated a bacillus from dead rats found in a ship arriving in Bristol which, though very like the plague bacillus, really stood as regards its cultural characters between the *B. coli* and the *Bacterium lactis aërogenes;* and Skschivan in the experiments just referred to, found that a plague-like disease of rats might be caused by the *B. mucosa capsulata* and by bacilli of the coli group. Lochmann has also found a new bacillus of the coli group which is pathogenic for mice and guinea-pigs, and Edington found in rats suspected to be dead of plague a bacillus very like the plague bacillus, but differing from it in its morphological characters and in its pathogenic effects on other animals. Galli-Valerio has pointed out that the *B. pseudo-tuberculosis rodentium* is very like the plague bacillus morphologically and culturally, and that confusion in the diagnosis

of plague by the inoculation of guinea-pigs might result if the former bacillus were already present in the guinea-pigs ; but Favre says that in spite of their known resemblance it is not difficult to distinguish them. Dieudonné draws attention to the value of the speedy appearance of involution forms in Hankin's salt agar medium as a means of differential diagnosis between the plague bacillus and other similar kinds, and Maassen, among others, corroborates the value of the skin-rubbing method for the discovery of the bacillus in suspected material, especially when such material is contaminated with other microbes, and when it is desired to study the vitality of the bacillus in fæces or other matter. He found that in the dried excrement of rats the plague bacillus did not remain alive more than one day, but that if the excrement were kept from drying it could retain its vitality up to the fourth day. Dieudonné says that the vitality of the plague bacillus in different media outside the body depends on the number of saprophytic organisms present and on the surrounding temperature ; the greater number of saprophytes and the higher the temperature, the shorter is the life of the bacillus. The plague bacillus is indeed but very slightly susceptible to cold, and Toyama has shown that a plague culture after two months' exposure to the cold of winter in Tokio showed no difference in growth from a similar culture kept in an incubator, and its virulence after three months was unchanged. whereas the virulence of a control culture kept in the incubator had decreased considerably after 84 days. Drying, however, kills the bacillus quickly, and Dieudonné points out that alternations of dryness and moisture are also very injurious to its vitality. Inghilleri found that in distilled, sterilized water the plague bacillus can retain its vitality for 60 to 75 days at 35° C., and for 30 to 60 days at 18—20° C. In some of the potable waters of Rome the bacillus was alive in one case after 35 days, in another after 33 days, and in another after 28 days. Burnet however remarks that the experiments of Inghilleri were made under very artificial conditions, and that the plague bacillus retains its vitality better under natural conditions than under artificial ones. According to him if the experiments are made under conditions as nearly as possible approaching those which would be met with in nature, living plague bacilli can live in water 120 days.

Mode of spread. Rats and other animal carriers.—According to Dieudonné the spread of plague results through the agencies of human beings and human traffic on the one hand and through rats on the other. The consensus of opinion of 37 correspondents with experience of plague epidemics, quoted by Simpson in his report on plague in Hong Kong, favoured the view that the infection was carried from place to place by individuals and from house to house by rats. Thirty of the correspondents had found that the plague outbreak was preceded by a mortality among rats, and only four that the rat mortality was simultaneous with the plague outbreak. Dieudonné gives several instances in support of the view of Koch and others that plague is essentially a disease of rats, which only after some time spreads to man from these animals. The German Commission were of opinion that rats take an essential share in the maintenance of the disease in its endemic centres, an opinion which finds support in the important observation quoted by Dieudonné that rats can suffer from a chronic form of the disease, so that plague germs can remain for a long time in the bodies of these animals, and from time to time originate an epidemic among them. Rabinowitsch and Kempner, in reporting on the plague epidemic at Odessa, considered that the disease was spread directly by rats, and Gamaleia that it was spread through the medium of cereals infected by the urine and fæces of plague-infected rats. On the other hand Flexner, in an account of the epidemic at San Francisco, says that rats took no part in the spread of the disease there, and no sick or dead rats were found. In the outbreak of plague at Manilla, in the Phillipines, rats were caught, labelled, and sent alive to the laboratory to be examined—a better procedure than taking only dead rats. During the first two weeks in which this method was carried out, 1·8 per cent. of the rats caught were found infected, and during the month of October 2·3 per cent. Out of 3,274 dead rats examined in connection with a recent outbreak of plague at Brisbane only 25 were found infected. The importance of ship rats in the spread of plague has been drawn attention to by Kossel and Nocht, Skschivan, Nocht and Giemsa, Dieudonné, and others. Nocht and Giemsa say that for the spread of plague from harbour to harbour the rats on board sea-going ships must be held responsible, and they agree with Kossel and Nocht in saying that scarcely a single instance of an outbreak of plague in a sea-port town has been traced to infected human beings. Skschivan is also of the same opinion as to the importance of ship rats in the spread of the disease, though he says that ship-rat plague is not always followed by human plague, and that in the East rat and human plague are not always coincident. Mice can also take part in the spread of plague, and Gotschlich, Thompson, and others have given instances in which plague-infected mice were found. Three mice were also

found infected with plague bacilli in the Brisbane outbreak referred to above. Simpson found in Hong Kong that pigs, calves, buffaloes, sheep, hens, ducks, geese, turkeys, and pigeons are, in addition to rats, susceptible to plague, and especially so when fed with plague material. His experiments also showed that the infective material of a plague rat can cause plague in monkeys by feeding or by inoculation, and the infective material of a monkey with plague can give rats plague. Wilm had previously observed that spontaneous plague infection sometimes occurred among pigs in Hong Kong. The German Commission, however, found that Indian pigs are almost completely insusceptible to subcutaneous inoculation of plague bacilli, and Di Mattei made a similar observation as regards the pigs in Italy. Albrecht and Ghon also fed young pigs with large quantities of plague material for some weeks without result, and they also obtained negative results by different methods of infection of plague bacilli with hens, geese, and pigeons.

Mode of infection. Fleas and other insects.—Dieudonné says that the communication of plague from man to man can occur either directly from a diseased man or indirectly through the medium of infected dwellings, linen, clothes, or utensils. From the point of view of direct infection all the severe septicæmic cases are dangerous ; but the most so are the lung cases, in which the sputum, loaded with bacilli, is sprayed about when the patient coughs or even when he speaks. Mild cases which may take the form of only a simple bronchitis, and convalescents from the pneumonic form of the disease, whose sputum may contain plague bacilli for weeks or even months after convalescence has begun, also play a large part in the spread of the disease. The method by which plague is communicated from the rat to man is not yet known. Above all, says Dieudonné, plague-stricken rats are dangerous in that they evacuate plague bacilli with the urine and fæces which they deposit in every room into which they go, and the bacilli thus spread in dark damp rooms are capable of living for a long time. The opinion of Simond that fleas can communicate plague from rat to rat and from rat to man has been opposed by Galli-Valerio, Nuttall, Kolle, and others. Gauthier and Raybaud, however, report that they have succeeded in infecting a healthy rat by the bites of fleas taken from an infected one, and also that the fleas of rats will bite human beings. Tiraboschi divides the fleas infesting rats into those that do not bite man (*Ceratophyllus fasciatus* and *Ctenopsylla musculi*) and those that do (*Pulex serraticeps* and *Pulex irritans*) ; only fleas of the latter kind are therefore capable, according to him, of communicating plague from rat to man. Tidswell made a collection of rat fleas in connection with the plague epidemic at Sydney. Out of 100 fleas obtained 10 were identified as *Pulex fasciatus*, 8 as *Typhlosylla musculi*, 1 as *Pulex serraticeps*, and 81 as *Pulex pallidus*. *Pulex pallidus* and *Pulex fasciatus* bit human beings in laboratory trials. All of 50 specimens of fleas caught on rats in India examined by Captain Liston, I.M.S., were identified as *Pulex pallidus*, and of 28 specimens caught on man 27 were identified as *Pulex irritans* and one as *Pulex canis*. Dieudonné says that experience in Bombay and in other epidemics goes against there being any considerable danger from the bites of infected fleas, while the fact that plague seldom occurs among the attendants in plague hospitals points also to the fact that mosquitoes play little or no part in the spread of the disease. He considers, however, that fleas and other biting insects may be of some significance, in that the wounds caused by their bites may afford a point of entrance for plague germs present on their bodies or legs, or even on the clothes of the person bitten. Flies are also of some significance in that they can convey plague bacilli from sputum or excrement on to utensils and food.

Measures against rats.—The Clayton process for the disinfection of ships and the destruction of ship-borne rats has been favourably reported on by Calmette and Hautefeuille, and adopted by some of the large shipping companies. Freer, however, says that the employment of sulphurous acid gas has many disadvantages, and can be used only if all the stores and a considerable amount of woodwork are removed, and that it will not kill rats unless it is very condensed. Nocht and Giemsa also point out that many kinds of merchandise, especially fresh fruits, flour, and meat, take up large quantities of sulphurous acid and are quickly changed by it ; also that by its repeated use the hulls of ships are affected, and the steel parts quickly and deeply rusted. They have invented an apparatus for the employment of carbonic oxide gas, which is free from these disadvantages. The apparatus was tried with success on some of the ships of the Hamburg-America line. Haldane had previously recommended the use of carbonic oxide gas, but his experiments were not carried out on such a large scale as those of Nocht and Giemsa. Abel has made experiments on the destruction of rats with the bacillus of Danysz, and considers that the method is a promising one, but requires to be experimented with more extensively. Oettinger considers that several different kinds of bacteria

are called by the name of the Danysz bacillus, but that none of them can have their virulence exalted by the method of Wiener in such a way as to make them practically useful in the destruction of rats. Colonel King, I.M.S., has reported favourable results in causing the disappearance of rats from houses and in preventing them from effecting an entrance to any house, by the use of a mixture of tar and sulphuric acid, which is spread in the entrance of all rat holes or in a circle round the building which it is desired to protect.

* These figures do not agree with those given by Provincial Sanitary Commissioners in their annual reports. In the case of the Punjab the figures here used have been supplied by the Chief Plague Medical Officer of the Punjab. In the case of the United Provinces they are those supplied by District Magistrates who obtain their figures mostly from special Plague Medical Officers. In the cases of the Central Provinces and Madras they are those supplied to the Local Governments.

Bengal.—The total number of deaths recorded as due to plague in Bengal during 1902 was 32,967 as compared with 78,629 during 1901. The Sanitary Commissioner remarks, however, that this decrease was probably more apparent than real, and was

evidently due to the inclusion under the heading of "fever" of numbers of deaths from the septicæmic form of plague which largely prevailed in parts of Bihar. Plague prevailed with the greatest intensity in Calcutta, where 8·58 per 1,000 of the population fell victims to it during 1902 against 9·29 during 1901. In Patna, where a ratio of 16·86 per 1,000 was recorded in 1901, a mortality of only 1·71 per 1,000 was recorded in 1902. The Civil Surgeon of Saran reports that there appeared to be two factors in the spread of the disease; the amount of human intercourse and the agency of rodents. The parts of the district most affected were along the lines of communication, especially the river and railways, and the more outlying and secluded parts were almost entirely free from the disease. Rats, mice, and squirrels all suffered severely from the epidemic, and were constantly found lying dead in infected areas. "Both these sources of infection are thoroughly appreciated by the people themselves and influence them in their efforts to protect themselves from the disease." The Sanitary Commissioner says that the feeling of the people was against anti-plague inoculation, and for this reason only a small number of inoculations were performed in the districts of Saran, Patna, and Darbhanga. Disinfection also, he says, is not generally liked by the people, but evacuation of infected houses is in great favour with them. This is done spontaneously and generally fairly thoroughly by the people themselves without outside interference, and the benefit of the timely exodus is most marked.

City and port of Calcutta.—The mortality from plague in the city and port of Calcutta was rather less during 1902 than during the two previous years. A special department, independent of the health department, undertook the administration of the disease and reliance was placed mainly upon disinfection. Eighty-nine vessels were boarded on arrival from plague-infected ports, but no case of plague was found on any of them. Among the crews and passengers of outgoing vessels no case was detected.

United Provinces.—In the United Provinces there was a great increase in the mortality from plague, 43,487 deaths being recorded from this cause during 1902, as compared with 9,778 during 1901. The disease was most prevalent in March and least so in July. Deaths were reported from no less than 34 districts. Among towns the highest death-rates were 4381 per 1,000 at Jaunpur, 36·69 at Cawnpore, 31·10 at Gorakhpur, 30·76 at Ballia, and 25·86 at Barhaj. The higher proportion of deaths among females than among males was attributed to the facts that native females spend more time inside their houses and courtyards than men and do not habitually wear shoes.

Punjab.—The mortality from plague in the Punjab during 1902 was more than 10 times as great as that of 1901 and accounted for no less than 175,645 deaths, a total which, with the exception of that of Bombay, is over three-and-a-half times as high as that of any other province in India during 1902. The epidemic broke out in the winter months of 1901, the number of deaths increasing month by month to a maximum in March and April of 1902. The disease was confined during the year chiefly to the central and thickly-populated portion of the province. In the district of Ludhiana 71 per 1,000 of the population died from plague, and in the districts of Umballa and Sialkot 30 and 26 per 1,000 respectively. Next came Jullundur, Gurdaspore, Hoshiarpur, and Lahore districts. The Civil Surgeon of the Ludhiana district gives instances of 22 villages in which the enormous death-rates of from 20 to 40 per cent. of the population were registered. As a rule rats were found dying in every village before the commencement of outbreaks of the disease among the inhabitants, and those villagers who on the discovery of rats dying left their houses and did not visit them again mostly escaped. In the whole province the recorded proportion of deaths from plague among males and females was approximately as 7 : 10.

Owing to the rapid extension of the area infected with plague in the Punjab in the winter of 1901–02, the impossibility of inducing the people to adopt measures of segregation and evacuation with sufficient thoroughness, and the consequent difficulty in rendering disinfection effective, the local Government obtained the sanction of the Government of India to a scheme for inoculation on a great scale. It was proposed to begin operations on the 1st September, 1902, and to inoculate seven millions of the people before the end of March, 1903. To do this every member of the provincial medical establishment who could be made available was employed, five medical officers were obtained from the military authorities, and 37 medical men were specially engaged in England. But the scheme was unfortunate from the beginning. Owing to the magnitude of the demand, the manufacturing laboratory was not at first able to supply

the quantity of prophylactic required, and the commencement of operations had to be deferred until the 1st of October, while the deplorable catastrophe at Mulkowal where, early in November, 19 persons died of tetanus after inoculation from the same bottle of fluid, not only brought operations temporarily to a standstill, but made the people unwilling to subject themselves to inoculation.

The results of the inoculation campaign in the Punjab, of which a detailed report is under preparation, are given in the following statement :—

Year.	Total number of plague—		Percentage of total deaths to total cases.	Total number of inoculations performed.	Inoculated persons.		Percentage deaths to attacks among inoculated persons.
	Cases.	Deaths.			Attacked.	Died.	
1902–03.							
1st October, 1902, to 23rd May, 1903.	299,303	178,849	59·8	480,737	4,667	1,158	24·8

North-West Frontier Province.—Only four deaths from plague were recorded in this province during 1902, all of which were said to have been imported from the Punjab. The measures taken to prevent the spread of the disease were attended with success.

Central Provinces.—The total number of deaths from plague officially recorded in the Central Provinces during 1902 was 459 as compared with nine in 1901. The Provincial Sanitary Commissioner, however, considers the number of deaths from this disease during 1902 to have been at least 1,061. The history of indigenous plague is confined to outbreaks at Loni and two other villages in the Nimar district, and outbreaks in the town of Burhanpur, the city of Jubbulpore, and the small town of Pulgaon in the Wardha district. The outbreak at Loni commenced on the 3rd of February and lasted until the 25th of March. In the case of this outbreak, as well as in that occurring in the town of Burhanpur, the infection was traced to infected areas in the Khandesh district. In Burhanpur the outbreak commenced at the end of October, and, despite active measures, became more and more severe and continued into the present year. At Jubbulpore plague was present some little time before it was officially recognised, and owing to the concealment of first cases by the people, the disease had obtained a firm hold of the town before measures against it were initiated. The endeavours subsequently made were unavailing and a widespread epidemic ensued.

Bombay Presidency.—The largest number of deaths from plague in any province was again recorded in the Bombay Presidency, the disease accounting for 184,752 deaths as compared with 128,259 deaths in 1901. The mortality from plague in this presidency during 1902 is the highest recorded since its first appearance in 1896. All the collectorates in the presidency, except Upper Sind Frontier, were affected.

City and port of Bombay.—In the city of Bombay 13,786 deaths from plague were recorded during 1902 as compared with 18,694 in 1901. The disease was present throughout the year, the month of maximum prevalence being March and of minimum prevalence July. At the inspections of outgoing and incoming vessels and of vessels lying in the harbour, 44 cases of plague were detected. Among the passengers and crew sent to the port observation camp, 28 developed plague and were transferred to the various hospitals in the city for treatment.

Berar.—In 1902 for the first time since the commencement of the present epidemic in India, plague made its appearance in Berar and caused 4,188 deaths. It is said that at first evacuation of houses was resorted to by the people only after the disease had wrought havoc among them, but that by experience they afterwards learnt that their only safety lay in vacating an infected village as soon as possible. Disinfection and "desiccation" were carried out to some extent in all infected areas, and much inoculation work was done. It was noticed that besides rats and squirrels, many monkeys died of plague.

Madras Presidency.—The total number of deaths recorded as due to plague in Madras during 1902 was 11,362 as compared with 3,035 in 1901. The only district, however, which was severely affected during 1902 was Bellary, in which 7,354 deaths

from plague were recorded, the district of Salem coming next with a total of 1,668 deaths. The Sanitary Commissioner says that the territory under the Government of Mysore continued to be a special danger to the presidency, in that excepting measures taken in the cities of Mysore and Bangalore, very little attempt at organisation for checking the spread of the disease exists in that area. He considers that the system of surveillance, without detention, of all travellers passing from infected areas to uninfected areas, so arranged that to whatever part of the Madras Presidency they journey, surveillance proceeds uninterruptedly for a period of 10 days, is fairly efficient. Where rural areas are imminently threatened by plague, special staffs composed of certificated sanitary inspectors are placed on duty, so as to strengthen the executive of the existing district staffs and thus keep each inhabited area under systematic observation. Railway inspection was used only where it was possible to protect a still uninfected area, and during the year 176 cases of plague were withdrawn from the railway trains at Jalarpet, the point where cases from the Mysore territory are received. The Provincial Sanitary Commissioner considers that experience in the Madras Presidency shows that man causes the rat to suffer and not the rat the man in the first place, that the area over which infected rats roam is usually small, and that recrudescence is by no means a natural feature of the disease, but a very natural result of apathy or of too optimistic treatment of an indigenously infected area.

Burma.—Only three imported cases of plague were detected in Burma during 1902. Only one of these cases was fatal, and a bacteriological examination yielded negative results.

Baluchistan.—In Baluchistan 30 deaths from plague were reported during 1902. No death was recorded during the previous year. Sonmiani, a small town on the sea coast, was the only place where an outbreak occurred. It is said that infection was brought from Karachi. The town was entirely evacuated and disinfected, and the outbreak, which had caused 28 deaths, ceased. The other two deaths occurred at Sibi, but both the cases were imported.

Rajputana and Ajmer-Merwara.—In Rajputana 149 deaths from plague were recorded during 1902 as compared with 185 during 1901. The disease appeared in the villages of Karnikot and Khuteta in the Ulwar State and in the village of Duthariya in the Marwar State. It is said that the deaths recorded as due to plague in Khuteta were in all probability due to cerebro-spinal meningitis and not to plague. Only one suspected case of plague, which terminated fatally, was recorded in Ajmer-Merwara.

Central India.—There was no plague anywhere in Central India in 1902 until the last week of September. The disease was very prevalent at that time in Khandesh and Nimar in the Central Provinces and probably spread from thence to Central India. The most severe outbreak occurred at Khasroad, a village in the Bhopawar agency. Evacuation of the infected portion of the village and disinfection of infected houses were carried out. During the year 1,275 persons were inoculated, of whom two were attacked by plague one month after inoculation.

Mysore.—The total number of deaths from plague recorded in Mysore (excluding Bangalore civil and military station) during 1902 was 26,301 as compared with 11,936 in 1901. "Desiccation" of the interiors of infected houses is said to have been introduced in various parts of the State, and "the result is being carefully watched."

Hyderabad State.—The mortality from plague in the Hyderabad State during 1902 was nearly 60 times as heavy as during 1901, the total deaths recorded amounting to 8,934. To this total the district of Aurangabad contributed 7,581, the district of Oosmanabad 1,089, the district of Kopbal 182, and the district of Raichur 74. In the remaining four infected districts eight deaths in all were recorded.

Fevers.

The total number of deaths recorded as having been due to fevers during 1902 was 4,279,551, or a ratio of 19·17 per 1,000 of population, as compared with a total of 4,174,919, or a ratio of 18·73 during 1901. The heading "fevers" includes the deaths from a large number of different causes, and it is not possible to say with any approach to

accuracy what proportion of the fever death-rate in India as a whole, or in any province, is due to malaria. The fact, however, that the malarial fever ratios for European troops, native troops and prisoners were all lower in 1902 than in 1901, is perhaps some indication that the rise in the ratio for fevers among the general population was not altogether due to an increase in malarial fever. A very large increase in the prevalence of plague occurred during 1902, and it is probable that, as in previous years, many deaths from plague were recorded as having been due to "fever." The greatest number of deaths from fever was recorded as usual during the last four months of the year, and the fewest in July. As compared with the previous year an increased number of deaths was recorded in all the months of the year except January, July, October and December, the greatest increase occurring in May. In Bengal the fever death ratio was the highest recorded since 1897, being also considerably higher than the mean ratio for the previous five years. The unusually high mortality from fever in April is attributed by the provincial Sanitary Commissioner to the fact that some of the deaths from plague, which was very prevalent at that time, were wrongly returned under the heading of fever. A mortality of over 30 per 1,000 was recorded from nine districts in 1902 as compared with four districts in 1901. Fevers were not so prevalent during 1902 in Assam as in 1901. The Sanitary Commissioner says that the decrease was well marked in both valleys, though certain districts in the Brahmaputra valley showed a rise, notably Darrang where the increase is suspected to be due to an increase in *kala azar*. The number of deaths attributed to *kala azar* in the Sylhet district has also increased considerably, apparently as the result of a special investigation having been made into the true extent of the disease there. In the Goalpara district, however, the number of deaths returned as due to this disease are very few in comparison with the number so returned in former years, in spite of the fact that this is the district in which malarial fevers are most prevalent. In the United Provinces the death-rate during 1902 was higher by 1·05 per 1,000 than that of 1901. During the year a circular, giving instructions for dealing with mosquitoes and their larvæ, was issued to all District and Municipal Boards, Civil Surgeons, and special health officers, and in some localities efforts were made to give effect to the suggestions, although no measures on a large scale were attempted. In the Punjab a further decrease in fever mortality occurred during 1902. The highest district ratios for the year were those of Hissar, Rohtak, Gurgaon, Delhi, and Karnal, all in the Delhi division. The unusual increase in the fever mortality of the Hissar district during the first quarter of 1902 is ascribed by the Civil Surgeon to cerebro-spinal fever of a very severe and fatal type which prevailed in an epidemic form during that period. The disease also prevailed during the first half of the year in the city of Delhi, and perhaps also in the Rawalpindi district. Trial measures for the prevention of malaria by the destruction of mosquitoes were carried out in Gujranwala and Gujrat, but with very little success owing chiefly to the outbreaks of plague in both the towns. In the North-West Frontier Province the death-rate from fevers was 4·69 per 1,000 higher than in 1901. In the Central Provinces the mortality from this cause fell slightly. The Sanitary Commissioner considers it probable that the large majority of the deaths ascribed to fever were due to fevers of malarial origin. Systematic operations against mosquitoes, based on the recommendations of the conference on malaria held at Nagpur in January, were carried out in certain selected towns. In Berar the fever death-rate was slightly reduced. Some municipalities were selected as areas for experiment in the destruction of mosquitoes, but the provincial Sanitary Commissioner does not anticipate that much will be done in this direction as the finances of the municipalities are so taxed by the strain of plague expenditure. The mortality from fevers in Lower Burma was slightly in excess of that of 1901, but considerably lower than the mean ratio for the previous five years. The provincial Sanitary Commissioner remarks that the figures probably include a considerable number of deaths from dengue which was prevalent throughout the province from April to September; but dengue, though very contagious, is by no means a fatal disease, and the deaths from this cause would hardly be likely to appreciably affect the total fever death-rate. In the Madras Presidency the mortality ratio from fevers was slightly lower during 1902 than during 1901. The mortality in the town of Madras decreased from 18·3 to 14·7 per 1,000, but this town still has one of the highest fever rates in urban areas in the presidency and compares very unfavourably with other large towns in India, such as Calcutta, where the fever death-rate during 1902 was only 6·59 per 1,000, and Bombay, where it was only 6·30. The Sanitary Commissioner of Madras is apparently unable to account for this high rate in Madras town, and remarks that, in the absence of registration supported by medical diagnosis, it is, of course, impossible to ascertain what proportion of fevers in Madras town are due to malaria or to typhoid and other possibly

unnamed fevers. Dengue was prevalent in several localities of the presidency, but it did not add appreciably to the mortality. In Bombay the fever death-rate declined as compared with 1901, but high ratios were recorded in Ahmedabad and five other collectorates, apparently due, in the provincial Sanitary Commissioner's opinion, to a certain extent to famine causes. Although a high total death-rate may be the result of famine, this cause does not necessarily produce a high fever death-rate, and it is evident from a consideration of the statistics supplied by the Sanitary Commissioner that in some at least of those collectorates the high fever death-rate was simply due to the fact that nearly all the deaths which occurred were recorded under this heading.

Sale of Quinine.—In Bengal there was a considerable increase in the number of five-grain pice packets of quinine sold during 1902, 34,114 parcels each containing 102 five-grain packets being disposed of as compared with 30,593 parcels during 1901. This increase is considered to have been due to the much greater prevalence of fever during 1902 than during 1901.

In Assam the sale of quinine decreased all over the province probably because the year was less malarious than usual. In the whole province 1,434 parcels were sold as compared with 1,717 in 1901.*

In the Central Provinces the sale of quinine showed a steady increase, 2,681 parcels each containing 102 five-grain packets being sold during 1902 as compared with 2,050 in 1901. In the year 1901 all sales were effected through the agency of post offices, but during 1902 sales were also made through the agencies of schoolmasters, stamp-vendors, and *patwaris*.

The number of five-grain packets of quinine sold during 1902 in the United Provinces was 224,999. Of these 157,820 packets were sold at post offices, 24,093 by vaccinators, and 43,086 by landlords. Quinine was sold at post offices in all districts except Almora and Etah, but it was sold by vaccinators only in 22 and by landlords in eight districts.

It is said that quinine was gratuitously distributed in 13 districts of the Punjab, but the only references to the sale of quinine contained in the provincial Sanitary Commissioner's report are to the effect that Civil Surgeons have no concern with the sale of pice packets of quinine at post offices, and that since December the work of selling quinine to post offices for sale to the public has been transferred to the Lahore Central Jail.

* *i.e.*, 146,268 and 175,134 five-grain packets.

In Burma the sale of quinine through the post office, by private vendors, and by vaccinators, was steadily continued, and 179,708 five-grain packets at three pies each were sold during 1902, as compared with 158,385 during 1901.

Details are wanting regarding quinine sales in the North-West Frontier Province, Madras, Bombay, and Berar.

Dysentery and Diarrhœa.—The mortality ratio on account of dysentery and diarrhœa fell from 2·45 per 1,000 in 1900 and 1·11 per 1,000 in 1901 to the comparatively low figure of 1·06 per 1,000 in 1902. The ratio was also considerably below the mean ratio for the previous five years. The total number of deaths attributed to dysentery and diarrhœa during 1902 was 235,089 as compared with 247,054 during 1901. A decreased mortality occurred in all months of the year except April, May, June, and November. In Bengal the largest number of deaths occurred as usual in December, and as usual the disease prevailed with much greater severity in urban than in rural areas. The highest mortality was recorded in the district of Howrah (4·88 per 1,000), the districts of Puri, Cuttack, Calcutta, Patna, and Darjeeling coming next with ratios ranging from 3·87 to 3·07 per 1,000. The mortality ratios for Goalpara, Darrang, Sibsagar, and Lakhimpur in the Assam valley show the same large differences ranging from ·19 per 1,000 in Goalpara to 4·55 per 1,000 in Lakhimpur as have been noted in previous years; and investigation has not yet succeeded in suggesting a satisfactory explanation. The main factor which influences the results is the much higher death-rate among tea-garden coolies than among the rest of the population. The medical officer at Cachar considers the increased mortality in tea gardens to be due to the inclusion of deaths from advanced cases of beri-beri (so-called) along with deaths from diarrhœa, and the medical officer at Lakhimpur thinks that in tea gardens deaths from anchylostomiasis are frequently wrongly returned under the head of dysentery and diarrhœa on account of the similarity of symptoms in these diseases. The true explanation may possibly be that given by the medical officer at Darrang, who says that in tea gardens febrifuges are largely employed, and that deaths from "fever" are usually returned under the heading of "bowel disease," its common terminable condition; for the medical officer at Lakhimpur gives a table which shows that while the tea-garden coolie, from the statistical point of view, suffers about three times as much from bowel complaints as the general population, he suffers about three times as little from fevers, and the total loss from both complaints among both communities was about the same in 1902, viz., 14·47 per 1,000 for tea-garden coolies and 14·46 for others. In the United Provinces the death-rate from dysentery and diarrhœa was practically the same in 1902 as in the previous year. In the Punjab the

* Excluding Chhatisgarh Zamindaris. † Not available.

urban death-rate from dysentery and diarrhœa was four times as high as in the rural circles. The Sanitary Commissioner says that dysentery and diarrhœa and fever rates rise concurrently, and that in all except one of the towns where excessive death-rates from dysentery and diarrhœa were recorded, malarial fevers were very prevalent during the year. In the Central Provinces the death-rate from dysentery and diarrhœa was lower than in 1901, though in 10 districts a slightly higher rate of mortality was recorded. In the town of Nagpur the high mortality among children from bowel diseases during the rainy season was attributed to deficient rainfall and long breaks in the rains with corresponding increase in temperature. In Madras the death ratio from dysentery and diarrhœa was 1·01 per 1,000 as compared with 1·13 per 1,000 in 1901. In the town of Conjeeveram, which is supposed to have a good public water supply, one of the highest death ratios from this cause was recorded. In Berar, Bombay, Ajmer-Merwara, and Coorg the death-rates from bowel complaints were all lower than those of 1901.

Vaccination.

Vaccination in India,—The aggregate number of operations performed in 1902-1903 was 8,431,564, which is 395,120 more than in the previous year, and 557,172 more than in 1900-1901.

In all the provinces, except the Punjab, an increase was recorded in the numbers of operations performed ; and in the Punjab the decrease amounted to only 600 operations. Work progressed most in Bengal, the United Provinces, and Bombay ; and, in the Central Provinces, Assam, Burma, Berar and the North-West Frontier Province, considerably more operations were performed than in the previous year.

The number of primary operations performed during the year was 7,791,858, or 433,114 more than in 1901-1902, but the number of re-vaccinations fell from 677,706 to 639,706, a decrease of 37,994. In the Punjab the decrease in the number of re-vaccinations amounted to 72,105, and there was also a considerable falling off in the number of re-vaccinations performed in Berar, from 38,122 in 1901-1902, to 23,505 in 1902-1903.

The average degree of success obtained in the country generally was better than in either of the two preceding years. In primary operations and in re-vaccinations, respectively, the percentages of success in 1900-1901 were 94·5, and 64·4 in 1901-1902 they were 94·97 and 65·5, and in the year under review 95·10 and 68·20. As in the previous year the highest percentages of success in primary operations were recorded in Ajmer-Merwara (99·18) and in Bengal (98·11) ; the lowest was recorded in Burma (86·03) and Madras (89·08). The percentages of success in re-vaccination ranged from 88·41 in the United Provinces, 86·36 in Ajmer-Merwara, and 85·14 in the Central Provinces, to 48·15 in Burma and 16·50 in Berar.

At dispensaries 208,733 operations were performed as compared with 210,277 in 1901-1902. In six provinces an increase in the number of operations performed was recorded, and in four a decrease. In two provinces, Berar and Ajmer-Merwara, no vaccination work is done at dispensaries. In Bengal the number of dispensary vaccinations decreased by 12,830, but it was still the province in which by far the largest number of operations were performed, Assam, the Central Provinces, and Madras coming next in order. In the Punjab only 206 operations were performed at dispensaries.

The average proportion of the population successfully vaccinated during the year was 33·14 per 1,000 as compared with 31·36 per 1,000 in 1901-1902. An increase in the proportion protected was recorded in all Provinces, Berar coming first with an increase of 12·8 per 1,000, the North-West Frontier Province and Coorg following next with increases of 9·93 per 1,000 and 9·27 per 1,000 respectively. The proportion of successful vaccinations per 1,000 of population was highest in Coorg, Assam, and Berar, and lowest in Bombay.

On the supposition that 40 children were born for every 1,000 of the population, 39·15 per cent. of them were protected by vaccination during the year as compared with 33·41 per cent. in the previous year, the percentages varying between 91·76 in Berar, 63·58 in the Central Provinces, 57·40 in Ajmer-Merwara, and 13·61 in Coorg.

The mean number of operations performed by each vaccinator in the year ranged from 3,527 in Berar and 3,365 in the North-West Frontier Province, to 999 in Assam and 866 in Ajmer-Merwara.

The average small-pox mortality was ·51 per 1,000 as compared with ·40 per 1,000 in 1901-1902. The death-rates ranged in the provinces from 1·26 per 1,000 in Assam, where there were 6,673 deaths, ·77 in Bengal, where there were 57,430 deaths, and ·7 in Madras where there were 24,967 deaths, to ·01 in Ajmer-Merwara, where only 3 deaths from small-pox were recorded.

* For the calendar year.

The aggregate cost of the Department was Rs. 11,65,756, or Rs. 33,499 more than in 1901-1902. The average cost of each successful case works out to 2 annas and 5 pies, against 2 annas and 6 pies in the preceding year. The greatest cost of each successful case was 8 annas and 9 pies in Bombay, Burma coming next with a cost of 4 annas and 5 pies, and Coorg next with 4 annas and 3 pies. In Bengal the cost of each successful case was only 1 anna and 2 pies.

Experiments regarding the preservation of calf lymph.—During 1902 and 1903, experiments were carried on in the Punjab by Captain W. F. Harvey, I.M.S., for the purpose of determining the relative efficacy and suitability of vaselinated and glycerinated vaccine lymphs derived from the buffalo calf.* Many of the experiments depending upon the results obtained by using the two preparations as vaccines were rendered of little value by conditions that had not been foreseen ; but it was found that, with properly prepared glycerinated lymph and careful vaccination, success at the rate of 99·81 per cent. was obtained in 5,166 cases of which 4,324 were inspected by Captain Harvey personally. Glycerinated lymph presents the following advantages over vaselinated lymph.

Glycerine is easier to mix with vaccine pulp than is vaseline, and, in consequence, the results of vaccination with glycerinated lymph are more likely to be uniform.

Glycerinated lymph rids itself of extraneous micro-organisms, vaselinated lymph does not. Glycerinated lymph is fit for use after a fortnight's storage ; and after a month's storage, the only organisms remaining were spore bearing bacilli and a large micrococcus, both of which can, it appears, be excluded if due care is taken of the vaccinifer.

Glycerinated lymph gives rise to a characteristic scab, whereas the scab which follows the use of vaselinated lymph, owing to the inflammation which it sets up, is usually composed of inspissated pus.

Glycerinated lymph appears to be more capable of resisting the effects of a high temperature than vaselinated lymph.

Captain Harvey found also that there was practically no difference in the results obtained by vaccinating with a mixture consisting of 1 part of vaccine pulp diluted with 2 parts of 50 per cent. glycerine, and with a mixture of 1 part of pulp diluted with 4 parts of 50 per cent. glycerine ; the use of the latter is, of course, the more economical.

Bengal.—The total number of operations performed in Bengal during the year 1902-1903 was 2,781,972, as compared with 2,662,826, in the previous year, and 2,346,311 in 1900-1901. Primary cases numbered 2,592,177 and re-vaccinations 189,795, the corresponding figures in the previous year being 2,529,778 and 133,048.

In both classes of work, therefore, a larger number of operations were performed. The success attending the work was also somewhat better, 98·11 per cent. of the primary cases and 68·07 per cent. of the re-vaccinations proving successful, while in the previous year the rates per cent. were 98·01 and 67·07 respectively.

The aggregate increase of 119,146 operations was not equally distributed over the whole province : 32 districts show an increase and 17 districts a decrease as compared with the previous year. Striking increases were recorded in the districts of Puri, Sonthal Parganas, and Midnapore. In Puri 35,266 more operations were performed than in the previous year, and in the two other districts mentioned the numbers were increased by over 23,000 cases. The increase in Puri is said to have been due to the employment of a larger number of vaccinators by the District Board, and in the other two districts to the prevalence of small-pox in them, which disposed the people to resort to vaccination. A remarkable decrease occurred in the number of operations performed in the district of Mymensingh, the number being 50,999 less than in the previous year. This decrease is attributed to the fact that a very large number of persons were vaccinated in the previous year on account of the epidemic of small-pox which prevailed at that time, while it is believed that the number of operations in the previous year were overstated. In other districts where decreases occurred, the causes assigned were generally the prevalence of malaria or cholera.

During the year under review it is estimated that 36·05 per cent. of the infants under one year available in the province for vaccination were protected, as compared with 32·06 per cent. in the previous year ; while in the municipalities the percentage of protected infants was 72·3. This figure compares favourably with those of recent years, but in some municipalities the rate of infant vaccination is still very low, notably in Calcutta where only 2,626 infants under one year of age were successfully vaccinated out of 7,976 who were available.

*A short account of a similar investigation made by Dr. Srinivasa Rao of Mysore will be found in the *Comptes Rendus* of the Thirteenth International Medical Congress—Section de Bactériologie et Parasitologie, page 96

Small-pox again prevailed in epidemic form during 1902, the total number of deaths amounting to 57,430 and the ratio per 1,000 of population to ·77 as compared with a ratio of ·50 per 1,000 in the previous year.

During the year 214,764 primary vaccinations were performed with calf lymph, 399,205 with lanoline lymph, and 1,978,208 by the arm-to-arm process, the percentages of success by each of these methods being 98·13, 96·75, and 98·38, respectively.

The Nepal Durbar and the Sikkim State received, respectively, 555 and 705 grains of lymph during the year. That supplied to the Nepal Durbar is reported to have given very good results.

With regard to the lymph supply of the province it has been arranged that the Calcutta vaccine depôt will no longer supply lymph to the Calcutta Corporation, and as this sets free a larger supply for the districts, the local authorities have decided that there is no immediate necessity for establishing vaccine depôts in Orissa or at Pusa.

Assam.—The operations during the year numbered altogether 304,121, of which 291,332 were primary operations and 12,789 re-vaccinations. In the previous year the total amounted to 280,827, the number of primary operations being 271,415 and the number of re-vaccinations 9,412, so that the figures for the year under review show a satisfactory increase of both classes of work. The recorded percentage of success in primary operations was 97·90 against 97·48 in the previous year, but in re-vaccinations the percentage of success fell from 81·09 to 77·81.

Excluding the hill districts where births are not registered, there were 143,769 infants under one year of age available for vaccination during the year ; among these 46,853 vaccination operations were actually performed, giving a protected rate of 32·59 per cent. for the plains districts as compared with 32·60 per cent. in the previous year. In the towns, where the Compulsory Vaccination Act is in force, more than 80 per cent. of the children available for vaccination were protected.

The amount and quality of the work done at the Animal Vaccine Depôt at Shillong was very satisfactory. The total number of tubes loaded with vaccine was 401,870, as compared with 395,317 in the previous year, and 387,557 in 1900-1901. The quality of the lymph was generally excellent throughout the year, although unfavourable reports were received from the Sylhet and Sibsagar districts regarding one supply. The vesicles of the calf from which this supply was taken were stated to have appeared to be as good as usual, and the reason why the lymph proved bad was unknown. A few experiments regarding the length of time during which lymph preserved in lanoline remains efficacious are reported by the provincial Sanitary Commissioner. The experiments showed that the lymph as manufactured in Assam, becomes ineffective after having been kept for a month or at the outside six weeks.

Inoculation still continues to find favour with the inhabitants of some parts of the province, especially with those of the Cachar and Sylhet districts.

United Provinces.—Including those at dispensaries, the total number of operations performed in the United Provinces in 1902-1903 was 1,665,253, as compared with 1,580,19 in the previous year. Of this number 1,562,070 were primary cases and 103,183 re-vaccinations, the percentages of success being 97·90 and 88·41, respectively, as compared with 96·02 and 81·55 in the previous year. It is satisfactory to note that despite the greater prevalence of plague in this province during the year under review, the figures show an improvement under all heads as compared with those of previous years. Vaccination in municipalities shows a decrease of 5,365 successful primary operations as compared with 1900-1901, and a proportion of 34·74 persons successfully vaccinated per 1,000 of population as compared with a proportion of 35·89 in the preceding year. In some of the worst protected municipalities, such as Cawnpore, Fyzabad and Gorakhpur, the low rate was attributed to the prevalence of plague.

Of 95,646 infants under one year of age estimated as available for vaccination in the municipalities, 87,725 were successfully operated upon.

Bovine lymph depôts were maintained, as usual, at Lucknow, Bahraich, and Allahabad. The total number of primary operations performed with pure calf lymph was 21,065, the percentage of success being 98·73. In 4,408 operations performed with lanoline lymph the percentage of success was 96·88.

The construction of the buildings for the central calf lymph depôt at Patwa Dangar has been commenced, and it is expected that the depôt will soon be in working order.

Punjab.—The total number of operations performed in the Punjab during 1902-1903 was 667,544 as compared with 668,144 in 1901-1902. The number of primary operations

rose from 511,121 to 582,626, while the number of re-vaccinations fell from 157,023 in 1901-1902 to 84,918 in the year under review. The increase in the number of primary vaccinations was due to the resumption of work in the plains districts where, in the previous year, it had been thought desirable to restrict vaccination operations on account of the prevalence of plague. The fear that anti-plague inoculation is to be carried out under the guise of vaccination appears, however, to be felt more by the inhabitants of districts where there is little or no plague than by those of districts where the disease is rife, and the large decrease in the number of re-vaccinations is attributed mainly to the fact that the inhabitants of the Kangra district and Simla Hill States, fearing that they would be subjected not to vaccination but to anti-plague inoculation, refused to have any operations performed.

The percentages of success as compared with those of the previous year rose from 93·92 to 95·36 in primary cases, and from 58·47 to 61·04 in re-vaccinations.

The numbers of primary operations and re-vaccinations performed in the Native State of Patiala were 45,088 and 9,707 ; in Kapurthala 6,207 and 39 ; in Faridkot 4,289 and 1,632 ; and in Nabha 866 and 1. The percentages of success in primary operations ranged from 98·63 in Patiala, to 88·68 in Nabha.

The number of children available for vaccination in towns was computed to be 59,365 ; of these 37,103, or 62·50 per cent. were protected. The Vaccination Act was not extended to any new town during the year, and in Delhi, Jullundur and some other towns a very large number of children remained unprotected. The prevalence of plague in many of the towns doubtless interfered to some extent with the work, but the provincial Sanitary Commissioner is of opinion that the chief causes of the slow progress of vaccination in the towns are the apathy of the people and the want of interest shown by members of municipal committees.

North-West Frontier Province.—There was a marked improvement in the primary vaccination work carried out in this province during 1902–1903 as compared with that of the previous year ; a total of 82,352 primary operations being performed against 63,321 in 1901–1902. The number of re-vaccinations increased from 7,672 to 7,941. The percentage of success in primary cases rose from 91·03 to 93·54, but in re-vaccinations it fell from 75·18 to 69·84.

Of the 10 municipal towns in the province the Vaccination Act is in force in two only, viz., Dera Ismail Khan and Bannu. In Peshawar city out of a total of 1,688 children under one year of age available for vaccination only 942, or 55·81 per cent. were successfully operated upon. The extension of the Act to Peshawar city is, however, under consideration.

Both animal and preserved vaseline lymph were used, the former showing a percentage of success in primary cases of 93·4, and in re-vaccinations of 70·1, and the latter success at the rates of 89·5 and 74·0 per cent., respectively.

In the Kohat district efforts to convert inoculators to the principles of vaccination have not been successful, but in the Mardan sub-division several inoculators were induced to come in and learn how to vaccinate.

Central Provinces.—The figures relating to vaccination in the Central Provinces include the work of the Feudatory States vaccination establishment and all the dispensary operations in the province. In regard to the Feudatory States in the Chattisgarh Division, however, the figures given for the year under review relate to the work of nine months only, viz., from the first of April to the 31st of December, 1902. The total number of operations performed by all agencies during the year 1902–1903 was 464,051, of which 398,065 were primary cases and 65,986 re-vaccinations, the percentage of success in primary operations being 97·13, and in re-vaccinations 85·14. In comparing the results of vaccination during the year under review with those of the previous year the figures for Feudatory States must, for the reasons given above, be excluded. Excluding also the figures relating to vaccination operations performed in dispensaries, there were 339,139 primary operations in British districts and 44,390 re-vaccinations during 1902–03 as compared with 269,270 and 53,409, respectively, during the previous year. While, therefore, the number of primary operations increased by 69,869, the number of re-vaccinations diminished by 9,019. The percentage of success in primary cases rose from 96·87 to 97·39, and in re-vaccinations from 83·56 to 85·14.

In all the districts except two, an increase in the number of primary vaccinations was recorded, a result which is attributed mainly to the very high birth-rate of 1902 combined with comparatively low infant mortality. Commendable activity was also displayed by the vaccination staff in some districts.

Of 357,679 children under one year available for vaccination in British territory during the year, 283,891 or 79·37 per cent. were successfully vaccinated. Low percentages were recorded in the districts of Chanda, Nagpur, and Jubbulpore, the poor results in the last two districts being attributed partly to the prevalence of plague. The provincial Sanitary Commissioner remarks, however, that plague was present in other districts without a corresponding decline in vaccination work.

Re-vaccination is said to be generally unpopular, and in the Damoh district it was interfered with by a rumour that it was really anti-plague inoculation. But the rates in different districts vary greatly, and it appears evident that in some districts sufficient attention is not paid to this class of work.

The Vaccination Act was not extended to any additional town during the year, and only about 65 per cent. of the available children under one year of age in the towns were successfully vaccinated, as compared with 73·40 per cent. in the previous year. Vaccination of young children is very defective in many municipal towns to which the Act has been extended, but it is said that improvement in this respect is anticipated during the next year.

About one-half of the operations in British territory were performed with fresh calf lymph, and the percentage of success was somewhat higher than in the previous year, being 96·09 against 95·63. The results obtained with glycerinated lymph were also more satisfactory than in 1901-1902, the percentage of successful cases being 95·25 as compared with 90·96 in that year. It is noted that while with the lymph prepared at Bhandara the percentage of success in primary vaccinations was 99·81, with that prepared at Seoni, failure resulted in three-fourths of the cases.

Berar.—The total number of operations performed during 1902–1903 in Berar was 141,064, or 20,646 more than in the previous year. Of this number 117,559 were primary cases and 23,505 re-vaccinations, which shows an increase of 35,263 primary operations and a decrease of 14,617 re-vaccinations, as compared with the previous year's work. The percentages of success were 96·8 in primary cases and 16·5 in re-vaccinations, the corresponding figures for the previous year being 96·6 and 18·3.

Vaccination in municipal towns is compulsory and the number of available infants under one year of age successfully vaccinated during the year under review compares somewhat unfavourably with the number so protected in the previous year, the percentages being 82·6 and 93·9 respectively. In three of the towns the decrease in the number of infants vaccinated is attributed to severe outbreaks of plague.

As in the previous year lanolinated lymph was used exclusively, and as the department was able to work below the sanctioned scale of establishment, the cost of each successful operation was nearly one anna less than in that year.

Madras.—An increase in the total number of operations performed by all agencies in the Presidency was again recorded during 1902-1903, the number being 1,332,209 as compared with 1,325,106 during 1901-1902. The increase occurred entirely in local fund areas ; in the municipalities there was a decrease of 11,210 cases, which is variously accounted for by the prevalence of plague, the disappearance of small-pox, the neglect of re-vaccination and paucity of cases available.

In six districts, against nine in the previous year, a decrease in the number of operations performed was recorded, the main reasons assigned being generally, as in 1901-1902, insufficiency of staff, the presence of plague, and insufficiency of lymph.

The total number of re-vaccinations fell from 89,910 to 81,447.

The percentages of success in primary cases fell from 89·41 to 89·08, and in re-vaccinations from 69·00 to 68·91.

In municipalities an average of 67 per cent. of the available children were successfully vaccinated as compared with 66 per cent. in 1901-1902, but in only 38 towns was the ratio of 75 per cent. or more, against 47 in the previous year.

A vaccine institute is about to be opened at Guindy.

Coorg.—Small-pox was less prevalent in Coorg during 1902-1903 than in the previous year, but the total number of operations performed rose from 9,772 to 11,407, of which 9,594 were primary cases, and 1,813 re-vaccinations, as compared with 8,416 and 1,356, respectively, in the previous year. At dispensaries 345 persons were vaccinated, against 320 in 1901-1902.

The percentages of success were 94·8 and 80·4 in primary cases and re-vaccinations, respectively, the corresponding figures for 1901-1902 being 93·5 and 74·2.

The average cost of each successful case of vaccination in the whole province was 4 annas and 3 pies, while in one municipality it was 7 annas and 10 pies, and in another 14 annas and 5 pies.

Bombay.—There were 537,744 persons primarily vaccinated and 41,141 re-vaccinated in the Presidency during 1902-1903 against 471,233 and 50,473, respectively, during the previous year—an increase of 66,511 primary cases and a decrease of 9,332 re-vaccinations. In the total number or operations there was an increase of 57,178.

In primary vaccination there was a decrease in the Southern and Sind Registration Districts, and in re-vaccination a decrease in all the districts except the Presidency Circle. This is attributed in the Southern district mainly to the presence of plague, and in the Sind district to a large amount of sickness.

The percentage of success rose in primary vaccination from 91·9 to 92·9, but fell in re-vaccination from 59·9 to 55·7. The percentage of cases in which the results were unknown rose from 6·71 in 1901-1902 to 7·80 in the year under review.

The number of infants successfully vaccinated in the Presidency (exclusive of Native States and Aden) was 364,513, or 71·85 per cent. of the available number.

The quality of lymph in use throughout the year was reported to be good. Both human and bovine lymph were used. About nine-tenths of the operations were performed with the former, the average percentage of success attained being 91·5. Animal lymph gave an average of 82·6 per cent. of success and was used in about one-tenth of the operations. With lanoline paste 5,525 operations were performed with a success of 84·18 per cent.

Burma.—The total number of operations performed during the year under review, including those performed at dispensaries, was 381,773, of which 354,629 were primary and 27,144 re-vaccinations ; the corresponding figures for 1901-1902 being 360,224, 333,657, and 26,567, respectively. Although the number of operations performed was greater than in the previous year, the ratio of success was lower, only 86·9 per cent. of primary cases and 48·15 per cent. of re-vaccinations being successful, as compared with 90·1 per cent. and 51·0 per cent., respectively, in 1901-1902.

The increase in the number of vaccinations occurred entirely in Upper Burma. The falling off in Lower Burma was ascribed to the predilection of the people for inoculation, to the indifferent class of men who seek employment as vaccinators, and to the closer supervision of their work.

The reason for the lower rate of success in operations is not stated, and the quality of the lymph supplied from the new vaccine depôt at Meiktila was said to be on the whole satisfactory. The results reported by Civil Surgeons were, however, not always in agreement, and a supply which was reported to have given successful results in 92 per cent. of cases in one place was said to have totally failed in all cases in another.

The Vaccination Act is in force in all municipal towns, but it is said that in Lower Burma the people fully understand that vaccination is not compulsory outside municipal limits, nor inoculation illegal, so that villages which willingly submitted to vaccination in past years now hold aloof altogether on one pretext or another.

Ajmer-Merwara.—There was a distinct improvement in the vaccination work carried out in this small province during 1902-1903 as compared with the previous year. The total number of operations performed during the year under review was 12,992, as compared with 10,841 in 1901-1902. Of this number, 12,948 were primary cases and 44 re-vaccinations, the corresponding figures for the previous year being 10,831 and 10, respectively.

Civil Sanitary Works.

Bengal.—Excluding Calcutta and including two new municipalities at Tallygang and Giridih, there were 157 municipalities in Bengal during 1901-02, as compared with 155 during the preceding year; and their total income, including an opening balance of £40,330, amounted to £344,160, of which 43·41 per cent. was spent on original and recurring sanitary works, 9·89 per cent. on roads, 5·58 per cent. on public safety, and 29·32 per cent. on all other requirements, the corresponding figures for 1900-01 having been 44·48, 9·14, 5·29, and 28·90, respectively.

The total expenditure on sanitary works amounted to £150,300, or 43·41 per cent. of income. The expenditure on the principal items was, roundly, 12½ lakhs on conservancy, 2½ lakhs on water-supply, and 1¾ lakhs on drainage. The expenditure under the head of conservancy shows an increase of £5,340, while that under water-supply and drainage decreased by £130 and £1,956, respectively. Only ten municipalities, or three less than in the preceding year, spent over 10 per cent. of their income on original sanitary works, 17 against 19 spent between 5 and 10 per cent., 74 against 77 spent below 5 per cent., while 56 against 46 spent nothing on this account.

The total cost of various new works carried out by municipalities, district boards, Government and private individuals, either completed or in progress, amounted in towns to £21,910, against £28,040 in the previous year, and in rural areas to £48,150, against £40,350. No new work of first class importance was either commenced or finished during the year.

Only one meeting of the Sanitary Board was held during the year. The principal subjects discussed at this meeting were the Howrah drainage scheme, the Gaya conservancy tramway scheme, and the septic-tank system of sewage disposal. The preliminary estimates for a drainage scheme for the Bihar Municipality were in course of preparation, but no detailed estimates for any project were prepared in the Board's office during the year.

Plans and estimates were considered and opinions given on twelve important water-works and drainage schemes, among them the extension of the Maniktollah water-supply scheme, which after revision by the Sanitary Engineer estimated to cost £12,270, was submitted to Government for sanction; the remodelling of the Darjeeling water-supply; the Mymensingh water-works extension scheme, and the Howrah drainage scheme. The Board dealt also with a number of miscellaneous references made to them by Government and by local authorities. The Sanitary Engineer paid visits to the municipalities of Dacca, Mymensingh, Howrah, Berhampore, Utterpara and Patna, either for the inspection of waterworks, sanitary works, or in connection with drainage schemes.

Assam.—Excluding four small towns which have no separate income, the total income of the municipalities, stations, unions, and towns in Assam was £14,530 as compared with £14,940 in 1901. The expenditure on sanitation amounted to £7,820 or 53·81 per cent. of the total income against 55·29 per cent. in the previous year.

Under conservancy £4,660 was spent against £4,860 in 1901; under water-supply £1,840 against £1,480; under drainage £640 against £730, while the balance was spent on minor sanitary works (£660), markets and slaughter-houses (£310), and vaccination (£78). The proportion of income spent by local bodies on sanitation ranged from 88·67 per cent. in the small town of Mangaldai to 22·58 per cent. in the town of Lakhimpur. Many minor sanitary improvements were effected by local boards in rural areas during the year, chiefly in connection with the extension and conservancy of the sources of water supply.

The Sanitary Board held two meetings during the year, and at other times business was conducted by the exchange of notes among the members.

United Provinces.—No details regarding municipal or district board income, or of the expenditure on sanitation, are furnished in the provincial report.

No new sanitary work of first-rate importance was undertaken during the year, but great advance was made towards efficiently draining sites and removing sullage water from the inhabited areas in the larger centres of population. At Allahabad, Cawnpore, Lucknow, Benares, Farrukhabad and Aligarh, large and important drainage works are under construction. At Benares the Dibdin system contact filters were in use throughout the year, except during the rains. They worked well, the effluent being of a high

standard and odourless. Other important projects in connection with drainage at Saharanpur, Kosi, Hathras, Haldwani, Deoband and Dehra Dun were either under consideration or actually sanctioned during the year under review, and at Mussoorie important sanitary improvements, towards the completion of which Government has granted half a lakh of rupees, were about to be commenced. In addition to this, the local Government has recognised the importance of an active sanitary policy as an integral part of the campaign against plague, and made a special allotment of £4,000 for experiments in improving the village water-supply, besides granting a subsidy of two lakhs of rupees to the more impoverished municipalities to assist them to carry out urgent sanitary measures which have been suspended for want of funds.

The amounts of filtered water supplied per head of population in the towns in which water-works are in operation were as follows. At Benares 15 gallons per head *per diem;* at Lucknow 5 gallons ; at Cawnpore over 13 gallons ; at Agra 9½ gallons ; at Allahabad 10 gallons ; at Meerut about 4 gallons ; at Dehra nearly 7 gallons ; at Mussoorie over 9 gallons ; and at Naini Tal 4 gallons.

Five meetings of the Sanitary Board were held during the year, when projects and estimates amounting to £72,930 for improving the sanitary condition of several municipalities were considered. A scheme for improving the drainage of Aligarh ; another for flushing the drains at Saharanpur ; and a third for constructing a *pucca* drain and culverts in Pilibhit were approved, and the Board also considered and recommended for sanction a project for branch sewers at Cawnpore, to cost £28,870. Various schemes for the extension and improvement of existing works for water-supply were also approved or considered, and plans for slaughter-houses and markets also received attention. The reports on the working of the Village Sanitation Act during 1901 were considered, and the Board passed a resolution that the improvement shown in the condition of sources of water-supply and in miscellaneous sanitary improvements of villages was satisfactory.

Punjab.—No details of municipal incomes or of the expenditure by municipalities on sanitary works are furnished by the Sanitary Commissioner of the Punjab in his report for the year under review.

The Sanitary Engineer gives a list of the projects prepared in his office or under his supervision during the year, as well as a list of sanitary works under construction. The sewerage system of Simla has been extended to serve all parts of the station, and there are now five distinct systems, which work independently, and lead to five different outfalls in the valleys below the station. A sufficient quantity of water is available in the streams at each of these outfalls in the driest time of the year to dilute the sewage to a strength of 10 gallons per head. At each outfall there will be disposal works where the sewage will be treated before it is discharged into the stream. The laying of all the mains (about 18 miles) was practically completed by the end of the year, but the disposal works were still in the experimental stage. At the main outfall an installation, consisting of a septic tank and a continuous filter, was under trial during the year under review. A larger installation to treat 40,000 gallons of sewage a day was under construction at the end of the year at the Kasumpti outfall. A project amounting to £6,150 for the drainage of the Simla bazaars was sanctioned and the work put in hand. An estimate for enlarging the existing distribution system of water-supply in Simla was also submitted for sanction. Work on the Amritsar water-works was commenced and was making good progress at the end of the year, but little or no progress was made with the drainage projects. In Umballa the extra-mural portion of the drainage scheme was commenced and was well advanced at the end of the year, and good progress was also made with the drainage works of Lyallpur ; at Lahore, sanction was obtained to the trial of a deep tube boring on Hughes and Lancaster's air lift system to raise water from a depth of 160 feet below ground surface.

The project sanctioned for increasing the water-supply of Kalka, at a cost of £2,860, was transferred to the Chief Engineer of the Kalka-Simla Railway for execution. The expenditure will be defrayed jointly by the Punjab Government, the East Indian Railway, and the Kalka-Simla Railway.

As regards rural areas, a considerable amount of activity was displayed by most district boards. The district board of Rawalpindi paid a reward of £10, which was distributed in three prizes, to village communities for improved sanitation, and similar rewards were offered by other boards. Sanitary note-books were in use in most districts, and are reported to supply valuable information to the inspecting officers regarding sanitary improvements.

The Sanitary Board of the Punjab met seven times during the year. The drainage schemes of the Simla bazaars, of Rawalpindi, Mooltan, Ferozepore, Gojra, Toba Tek Singh, and Sangla, as well as schemes in connection with the extension or improvement of the water-supplies of Simla, Amritsar, and Lahore, were considered and approved; the attention of the Board was also directed to the question of the selection of sites for new towns and other matters. To assist the execution of urgent sanitary works, shelved for want of funds, the local Government has decided to place an annual grant at the disposal of the Sanitary Board to enable it to contribute towards the cost of such works up to one-third the total cost. Further, an annual grant of £167 has been sanctioned to meet charges connected with experiments the Board may consider likely to assist in furthering the cause of sanitation and the execution of small works which would be delayed if formal sanction had to be obtained.

North-West Frontier Province.—The aggregate income in 1902 of the municipal towns in the North-West Frontier Province amounted to £34,480, the balance in hand at the beginning of the year being £10,800; and the amount expended on sanitary works was £8,940, or 25·9 per cent. of the income. This expenditure was incurred under the following main headings, the figures in brackets representing the expenditure under the same headings during 1901:—Conservancy establishment, £4,640 (£4,070); paving of streets, £622 (£680); roads and bridges, £1,020 (£836); drains and sewers, £1,010 (£1,060); water-supply, £1,480 (£1,930); construction of latrines, £76 (£68); widening streets, £60 (£190); repairs to latrines, £32 (£145).

The income derived from the sale of manure and street sweepings in all the municipal towns was £1,100, or £52 less than in the previous year.

No new work of capital importance was undertaken during the year, but in Peshawar city the water-supply was extended at a cost of £800, and a number of new surface drains constructed and old ones repaired at a cost of £700. In other parts of the province new wells were constructed, old ones cleaned, new pipes for drinking water were laid, and attention was given to various other minor sanitary matters.

No rewards appear to have been paid or *khilats* given to village communities during the year for special interest taken in sanitary improvements; and, so far, the village sanitary note-books do not appear to have been useful.

Central Provinces.—The total income of the district head-quarters municipalities of the Central Provinces during the year 1901–1902, excluding opening balances and receipts under the heads of "Grants and Contributions for general and special purposes" and "Extraordinary and Debt," amounted to £73,000 against £70,060 in the previous year. Of the total income, 31·78 per cent. was spent on sanitary works (original and recurring), 4·76 on medical relief, 0·07 on vaccination, and 1·37 on other sanitary requirements.

The chief sanitary works undertaken were in connection with the extension or completion of the water-supply projects of Nagpur, Bhandara, and Khandwa; £135 were also spent on the drainage survey of Nagpur. A number of minor works were carried out by municipalities, chiefly in connection with the construction and repair of drains and the improvement and extension of water-supplies.

As regards rural areas, expenditure was chiefly incurred in connection with general conservancy, including under this head the clearing of village sites.

During 1902 the Sanitary Board of the Central Provinces met in thirteen stations, the work done under their direction being chiefly in connection with the construction and repair of wells and the clearing of village sites.

Berar.—The estimated income of the municipalities in Berar during 1902 was £18,150, as compared with £17,580 in the previous year. The total expenditure, on sanitary measures under all heads, was £7,260, or 40 per cent. of income, as compared with 36 per cent. in the previous year. Outside the municipalities a total sum of £4,780 was expended by district boards, chiefly on drainage (£430), water-supply (£1,160), and "domestic cleansing" (£3,060). In 1900 the district boards spent £7,190, and in 1901 £5,140, so that the sum spent during the year under review shows a considerable fall.

The Sanitary Board met once at each head-quarter station during the year to consider what had been done by local bodies on the recommendations of the Sanitary Commissioner, as contained in his survey remarks in past years on towns and villages in the province.

Madras.—No details regarding income or expenditure are furnished in the provincial report. The Cocanada waterworks, begun in 1900, were well advanced at the end of the year under review, and Vizagapatam received its water-supply before the end of the year. Considerable grants were made to the towns of Madras and Ootacamund for the purpose of effecting sanitary improvements, and various schemes in connection with the water-supplies or drainage of Vellore, Saidapet, Masulipatam, Madura, Negapatam, Guntur, Kodaikanal, Dindigul, Adoni, Bezwada, Cuddapah, Ellore, Nellore, Trichinopoly, and Yercaud, were considered and dealt with.

Slow but steady improvement is being made in the conservancy of towns, which is largely attributed to the influence of certificated sanitary inspectors, of whom 110 are now employed by municipalities. Bacterial filters are gradually coming into use. Sewage farms or gardens continue to be worked with success where established. Cropping over nightsoil trenches, more especially as an object-lesson to ryots, is pursued at Erode, Cocanada, Rajahmundry, and Palni.

Steps have been taken to execute certain works in the vicinity of Guindy, to carry out experiments to ascertain what particular method of filtration of sewage would be most effective, and whether it would pay the ryot to erect rough filters for filtering town sewage to secure the effluent as manure.

The Sanitary Commissioner observes that a condition of stagnation has overtaken municipal efforts in regard to sanitary improvement since free grants to aid large works have been discontinued. Although conditions prevent help being given as easily as before, some progress was made during the year. The Presidential Government is, however, of opinion that in rural sanitation too little attention is devoted to the execution of works of permanent improvement, such as the efficient protection of wells, the construction of drains, and the provision of simple and serviceable latrines, while too large a proportion of the available funds is spent on establishment.

During the year the Board scrutinised the plans and estimates of 123 sanitary works, of which 52 were for municipalities, 66 for Local Fund Boards, 4 for the Collector of Salem, and 1 for the Collector of Madura, the aggregate estimated cost of the projects being £110,800.

The following were among the more important schemes and estimates considered:—

(1) The water supplies of Guntur (£34,230) and Tiruvannamalai (£11,800).
(2) A scheme to connect the Cuddapah waterworks with the Peddagadi natural reservoir (£10,000).
(3) Hospitals at Madura (£6,900), Bezwada, and Nandyal.

Coorg.—Particulars regarding the income and expenditure on sanitation of the municipal towns or of the district boards are not given in the provincial report; but beyond the construction of surface drains in the Mercara municipality no expenditure on sanitation calling for special remark was incurred.

No regular meetings of the Sanitary Board were held during the year, and the only question of importance to which attention was directed was the expedience of controlling wet cultivation within municipal limits as a preventive measure against the spread of malaria, and the extension of such cultivation was prohibited by a resolution of the Municipal Committee.

Bombay.—Excluding the Presidency town, there were 165 municipalities in Bombay during the year 1901–1902, and their aggregate income amounted to £414,910. Out of this sum £94,760 were expended on improving water-supply, on drainage, and on conservancy within municipal limits.

The income of the local boards during the year 1901–1902 amounted to £295,920, of which £10,740 were spent on water supply and drainage.

The Bombay Village Sanitation Act of 1889 has been introduced into 294 villages, but it is explained that owing to famine and plague, which claimed the attention of district officers, no progress was made.

The drainage works of Ahmedabad city, estimated to cost about 11 lakhs, were commenced.

The number of meetings of the Sanitary Board is not reported, but their attention during the year was occupied with projects and proposals in connection with the water-supplies of Poona city, Ahmedabad, Hyderabad (Sind), and Sukkur, as well as in connection with the drainage of Poona, Ahmedabad, and Nadiad.

The experiments on the Manjri experimental sewage farm were commenced in February, 1902. The septic tank and bacteria beds worked satisfactorily, and the crops irrigated by the effluent from the tank and by the filtrate from the bacteria beds were equally good.*

Burma.—The aggregate income of the 42 municipalities in Burma during 1902, including opening balances, amounted to £596,400, against £440,240 in the previous year. Out of this sum £293,770, or 49 per cent., were spent on sanitary works, as compared with 35 per cent. spent in 1901.

On rural sanitation £11,560 were spent during 1902, as compared with £9,960 during 1901.

At Rangoon a substantial addition was made to the water-supply by means of tube wells sunk in the Ahlone quarter. These wells yielded from 400,000 to 500,000 gallons of pure and potable water per day.

More than half the work on the Hlawga water-supply scheme was completed, and it was anticipated that the whole work would be finished in 1903.

A water-supply scheme for Akyab, at a cost of nearly 4 lakhs, has been submitted to the Sanitary Board for approval, and a scheme to improve the water-supply of Prome, at an estimated cost of over a lakh and a quarter, has been undertaken. Steady progress is being made in the surface drainage of Prome, which affords an example of carrying out the work piecemeal year by year till completed, instead of waiting indefinitely until funds can be found to carry out the complete work.

At Mandalay £1,320 were spent on surface drainage. In connection with water supply and conservancy, however, but little progress has been made. At Moulmein the water-supply scheme, to which reference has been made in previous reports, is under construction, and the work is said to be well advanced. The sinking of a tube well for the Shwebo Cantonment, at a cost of over £270, was sanctioned.

Three meetings of the Sanitary Board were held during the year—one at Akyab and two at Rangoon. At these meetings projects and estimates for sanitary work were considered, chiefly in connection with the water-supply and drainage of Akyab, the water-supply of the town of Myingyan, and the formation of railway towns at Khamonseik and Tharrowan. It is represented that local authorities do not at present regularly consult the Board.

General Remarks.

Red Sea Pilgrim traffic.—On account of the continued prevalence of plague at the end of 1901 the Government of India again found it necessary to impose restrictions with regard to pilgrimage to the Hejaz, and in view of the stringent quarantine rules of the Turkish Government and the inconvenience likely to be experienced by Indian pilgrims in Arabia, all who intended making the journey were again advised to defer their visit to another season. Karachi had been declared a plague-infected port, so it was closed for the embarkation of pilgrims, but arrangements were made at Porbandar in the Bombay Presidency, and at Chittagong, for the embarkation of pilgrims from areas unaffected by plague. At these two places alone could tickets for the voyage be purchased, and persons permanently or temporarily resident in any infected places were not permitted to embark. At Porbandar and at Chittagong observation camps were established, where the pilgrims, after disinfection of their clothing and other effects, were detained for the usual period of observation before embarkation. Pilgrims from uninfected parts of the Madras Presidency were kept under observation for 10 days, and their clothing and effects disinfected in camps established in the Presidency, and then despatched by sea from ports other than Madras to Porbandar.

Seven steamers carrying in all 3,609 pilgrims left Chittagong, and three steamers carrying 1,057 pilgrims left Porbandar. Two cases of small-pox occurred on one of the steamers from Porbandar, but the disease did not spread among the pilgrims, and no case occurred during the period of their detention at Camaran.

* A full account of these experiments will be found in the Agricultural Ledger, 1903, No. 2. "The Agricultural Value of City Sewage in India," by J. W. Leather, Ph. D., F.I.C., Agricultural Chemist to the Government of India, and J. Mollison, M.R.A.C., Inspector-General of Agriculture in India.

The total number of deaths among the Indian pilgrims at sea *en route* to Camaran was 23, the principal causes of death being senile debility, chronic heart and lung affections, and malaria.

The health of the pilgrims during their detention at Camaran was particularly good, and no plague, cholera, or other infectious disease made its appearance on the island. Among British Indians 13 deaths are reported to have occurred while at this place. It is said that the hospitals in the camps are very badly ventilated, that they have no water-supply laid on, and that they are without any lavatory, kitchen, or latrine, set apart for the sick.

A serious outbreak of cholera occurred in the Hejaz, but British subjects suffered only slightly.

One vessel only, the s.s. *Amahdi*, brought returning pilgrims to Bengal during 1902. She left Jeddah with 458 pilgrims, of whom 441 were landed at Diamond Harbour, and, after disinfection of their clothing and effects, were sent to their homes by rail. Seventeen deaths in all occurred on the ship during the voyage, but no one of them was due to infectious disease.

The pilgrims returning to Bombay numbered 3,570 and were conveyed by 13 vessels, some of which made more than one journey. During the voyage of the s.s. *Vadala* one case of small-pox occurred, the patient being removed to hospital on shore at Bombay. The remaining pilgrims were vaccinated and their clothing and bedding thoroughly disinfected. On the other pilgrim vessels there was no sickness of an infectious nature among the crew or passengers. Pilgrims whose homes were up-country or beyond the frontier were not allowed to enter the town, but were handed over to the Protector of Pilgrims to be sent direct from the disinfection sheds to their homes by rail.

The dues levied at Camaran on Indian pilgrims amounted to $68\frac{3}{4}$ piastres, equivalent to Rs. $12\frac{1}{2}$ at the rate of exchange current there; and the British Vice-Consul complains of the exceedingly unfair rate at which the amount due is converted into Indian currency; for while it appears that £1 sterling realises 109 piastres, its equivalent, when proffered in rupees, realises only $82\frac{1}{2}$ piastres. He recommends that, as the sanitary administration would not suffer by a fairer rate of exchange—the staff alone effecting a profit at the expense of the Indian pilgrims—the Sanitary Board at Constantinople should accept Indian coinage at the rate of 7 piastres to the rupee, as was formerly the case, instead of at the rate of only $5\frac{1}{2}$ piastres as at present.

The Delhi Durbar.—It is satisfactory that from the point of view of health, as well as in other respects, the Coronation Durbar at Delhi was a remarkable success. The collection on one spot of such a large number of natives from all parts of India rendered the importation of many cases of disease not only possible but probable, but it was effected with the occurrence of only a very few isolated cases of plague, which did not act as foci for the spread of the disease. The difficulties to be contended with in the creation on the bare plain of a large town of about 100,000 inhabitants, with four suburbs each containing from five to ten thousand people, for all of whom adequate arrangements for the supply of food, water, hospital accommodation, conservancy, &c., had to be made, were necessarily great, and it speaks well for the forethought and organising powers of the officials entrusted with the formation of the camps that all the arrangements worked so perfectly and that no hitch occurred. There was abundance of food, and the establishment of a public market by the Supply and Transport Department prevented prices in Delhi from rising much, if at all, above the normal. The supply of water in the central camps was unlimited; drawn from the Jumna above Delhi it was passed through the filter beds of the Delhi waterworks, and distributed through all the camps in pipes, so that contamination was impossible.

The conservancy arrangements, devised and carried out by Lieutenant-Colonel Thornhill Executive Sanitary Officer and Special Magistrate for the Durbar, were a perfect success. A liberal supply of latrines and of removal staff and plant, ensured the rapid disposal of the night-soil, and no accumulation ever occurred. Special roads, metalled and lighted, were made to the trenches, and as the carts worked at night, they were never in evidence.

The medical and sanitary arrangements were under the control of the Durbar Medical Staff, composed of Lieutenant-Colonel C. J. Bamber, I.M.S., as Administrative Medical Officer, Major F. Wyville-Thomson, I.M.S., as Special Health Officer, and Captain C. H. James, I.M.S., as Special Plague Officer, with a staff of two Assistant Surgeons and eight Hospital Assistants. In addition, each Provincial Government and

Native State brought its own medical officer and subordinates, with tents and equipment for a small hospital. An outdoor dispensary in charge of a Hospital Assistant had been established in the central camp in June for the treatment of natives employed on the Durbar works. This proved very useful, 5,000 cases being treated between the end of June and the end of January. A civil followers' hospital of 32 beds had also been established for all natives not otherwise arranged for, and for any overflow cases from the central camps. Separate arrangements were made by the Durbar Medical Staff for the segregation and treatment of cases of infectious disease; and to enable any outbreak of plague to be effectually dealt with, special regulations for the Durbar area were issued by the Punjab Government, giving the Central Committee general control over plague operations, and detailing the steps to be taken and the rules to be observed on the appearance of plague. Four segregation hospitals, fully equipped in every respect, were erected at different points. Fortunately these arrangements were never severely taxed, for only ten cases of plague occurred altogether. Although these cases occurred in eight different camps, in no instance did a second case follow the original one—a result which was doubtless due to the open-air life in tents, to the prompt recognition of the disease, and to the rapidity with which preventive measures were taken. The Durbar was practically free from other infectious diseases. No cholera appeared, and there were only five cases of small-pox, all in the military camps. As regards general diseases the camps were very healthy, and owing to the warm weather and freedom from rain and cold winds, chest diseases and pneumonia were not frequent or severe. The total number of cases treated in the civil followers' hospital and reported by the medical officers of the different camps (excluding all the troops) for the period from the 20th of December to the 10th of January, is shown in the accompanying table, but as the medical officers in many cases included their out-patients in the returns, the figures show a large excess over the actual number of serious cases in hospital.

—	Cases.	Deaths.
Malarial fever	1,564	4
Pneumonia	365	22
Other chest diseases	1,570	11
Dysentery and diarrhœa...	548	3
All other causes	2,828	29
Total	6,875	69

Malaria.—The important test experiments on measures for the prevention of malaria, which were commenced in Mian Mir in April, 1902, have been carried on up to the present time. A summary of the results obtained at the end of the fever season of 1902 was given in last report, and the narrative may be continued here. It will be remembered that, although the operations during the summer had brought about a reduction in the numbers of adult *anopheles* mosquitoes, yet, in spite of the checks upon their breeding, adult *A. culicifacies* and *A. Rossii* could be readily found in houses in the area of operations from July to November. During the latter month and the next the numbers of adult *anopheles* present in the houses and the numbers of larvæ in the breeding places decreased very rapidly, until at the end of December not a single adult *anopheles* could be found. A similar disappearance of adults was, however, observed in parts of the cantonment where no operations had been carried on, and in villages far removed from Mian Mir, so that their absence from houses in the area could not be ascribed to the effect of the operations. It was found, however, that although all adult *anopheles* had disappeared, a number of larvæ of *A. culicifacies* still remained alive, in a more or less "hybernating" condition, in permanent pools and other collections of water. The operations during the winter were therefore directed chiefly towards the destruction of all these "hybernating" larvæ within a wide radius of the area of operations. As no new batches of eggs or larvæ appeared in pools which had once been freed of them, this was a comparatively easy task,

and before the end of the winter all larvæ were destroyed within a radius of nearly two miles in every direction from the outer limits of the area. The limit of flight of *anopheles* mosquitoes is usually considered to be about half a mile, and as at the end of the winter no adults or larvæ were present within two miles of the area, it was a matter of considerable interest to see whether they would reappear in the area in the spring. This matter was not long in doubt, for at the end of April it was noticed that larvæ of *A. culicifacies* were being washed down into the area along the irrigation canals from places outside, and soon afterwards a few adults of this species were found in the houses of the area. Other methods by which adult *anopheles* mosquitoes reached the area were found to be (1) by flight over a comparatively long distance; (2) by the gradual spreading of adult mosquitoes in all directions from areas in which they were abundant; (3) by the introduction of adult *anopheles* into the area in carriages, carts, and other vehicles. When all these methods are taken into consideration it is not surprising that, in spite of the vigorous operations during the winter, *anopheles* mosquitoes were again almost as prevalent in the area at the end of May as they had been soon after the beginning of the previous year's work. The results of one year's work could not, however, be regarded as conclusive, and the task of controlling the breeding of *anopheles* mosquitoes was again taken up under more favourable conditions than in the previous year; for the staff of labourers knew their work, a large number of permanent breeding places had been done away with, and the canals had been thoroughly cleaned and repaired. At the commencement of July, Captain James handed over the control of the operations to Lieutenant S. R. Christophers, under whose direction they were carried on throughout the summer and autumn.

In the main the operations were similar to those of the previous year. The extent of area treated was, however, enlarged, and the destruction of breeding places carried out up to three-quarters of a mile from the Royal Artillery barracks and bazaar.

The operations against *anopheles* were mainly directed against larvæ, and the permanent removal of all breeding places within the area was, as far as possible, attempted. The nature of some of the breeding places (*i.e.*, more especially the irrigation channels) did not allow of this, and the larvæ were destroyed by kerosene oil at short regular intervals.

A most important part of the operations consisted, as in the previous year, of measures directed against the breeding in the irrigation channels of *A. culicifacies*, this species being apparently chiefly concerned in the spread of malaria in Mian Mir. The "cleaning" of the canals, which had been continuously kept up, had appeared to lessen the numbers of larvæ present, but, as the season advanced, larvæ of *A. culicifacies* became more and more abundant, and it was found necessary, in addition to "cleaning," to oil at intervals of 10 days the whole of the canals in the area. The effect of the measures was to almost completely prevent the presence of nymphæ in the canals treated. Young larvæ, however, appeared within a few days of each oiling and in *rapidly increasing numbers*. Indeed, it appeared evident that adults of *A. culicifacies* were increasing in number in spite of the operations.

The rain-formed pools which appeared with the first fall of rain on July 15th necessitated operations of a different kind. In these waters *A. Rossii* was alone abundant, while *A. culicifacies* remained confined to the canals and their overflows. As a result of the formation of numerous pools by the rains a remarkable increase in the numbers of *A. Rossii* took place, the increase being so rapid and striking as to merit the term "swarming"—a phenomenon well known in the case of some insects.

In dealing with rain-formed waters, drainage by means of earth-cut drains was found the most satisfactory of all the operations. By this means the area immediately around the barracks and bazaar became automatically free from standing water within 24 hours of the cessation of rain. In the outlying area one or other of the following operations was adopted, as seemed suitable:—Drainage, filling with earth, drying by baling out the water, and oiling with kerosene oil. From the great care taken to search out all breeding places it is extremely unlikely that any considerable source of *A. Rossii* was left within the area of operations.

Adult *anopheles*, however, both *A. culicifacies* and *A. Rossii*, appeared in increasing numbers in the bazaars and stables adjoining the barracks. The operations, therefore, though apparently very satisfactory as regards the destruction of larvæ, failed to show any demonstrable reduction of adults. This failure to affect the numbers of adults appeared to be mainly due to the passage of these from beyond the area of operations; and in two instances the undoubted flight of *A. Rossii* from 900 yards and three-quarters of a mile, respectively, was established.

The effect of the operations upon malaria was at first distinctly noticeable. As the fever season advanced, however, the operations appeared quite futile, and both among the troops and in the bazaar malaria became rife. During August and September (1903) the admissions for malaria among the Royal Artillery (troops within the area) were 24, or a ratio of 48 per 1,000 per month. During the same months the admissions among the British Infantry (troops outside the area) were 121, or 128 per 1,000 per month. There certainly appeared in these two months to be a reduction in the amount of malaria among troops living in the area of operations. In October, however, the Royal Artillery showed 318 admissions per 1,000 per month, as against 187 per 1,000 per month among the British Infantry, and for November 428 as against 278 per 1,000. The low figures of the British Infantry were probably due to the very strict quinine administration, but the number of admissions among the Royal Artillery were not diminished as compared with past years. The admissions for the whole season, from July 1st to November 30th, indeed, were considerably in favour of troops living outside the area as compared with those living within it, namely, 158 per 1,000 per month, as against 216 per 1,000 per month, respectively.

The effect of the operations upon malaria among natives was also very distinct in the early part of the season. As in the case of the troops, however, any appreciable diminution of the endemic index in October and November was not apparent. The incidence of malaria among the inhabitants of the bazaars corresponded with that among the troops. Thus, at the time (August and September) when the admission rate among the Royal Artillery was very low in comparison with that of the British Infantry, the endemic indices of two bazaars in the area were remarkably small as compared with the endemic index of untreated native communities. In October and November malaria among bazaar children in the area was as severe as in former years, and as in the British Infantry bazaar in the present year.

In addition to anti-mosquito measures, experiments were carried out as to the value of quinine administration to troops and native children. The experiments fall naturally under three heads :—

(1) Those conducted with strict scientific accuracy.
(2) Those under personal supervision, and as strictly carried out as is possible when dealing with large bodies of men.
(3) Those conducted either under supervision as ordinarily practised, or under no supervision at all.

A limited number (100) of the British Infantry soldiers, who had volunteered to take quinine regularly under supervision, were given 15 grains of quinine on two consecutive days each week. The number of admissions for malaria among these men was in striking contrast to the number among the remainder of the men who did not take quinine. During the time of the experiment (four weeks) two cases only were admitted out of the 82 men who had really taken quinine regularly. In neither of these cases were parasites found. Among the remaining 360 men, 67 cases of malaria were admitted into hospital.

After the conclusion of the above experiment the whole of the British Infantry were placed under compulsory quinine treatment, and the taking of quinine supervised with the greatest possible strictness. A distinct reduction in the admission rate resulted, but not so markedly as in the case of the smaller experiment.

Other troops in Mian Mir were placed upon quinine under the conditions noted under Class 3. No effect whatever was apparent.

Quinine was administered to the children of a native community (syce lines). It was found that in a small community of natives quinine administration to the children was by no means so difficult as might have been anticipated. A list of all the children living in the lines was readily obtained from the cantonment authorities, and it was found that the children took considerable doses of quinine for a reward of native sweets. The administration of quinine was rapidly effective in reducing the spleen rate among the children. During the administration of quinine the spleen rates of the children in these lines showed a reduction from 67·8 per cent. to 54 per cent. At the same time the spleen rate in two other native communities had risen from 36 per cent. to 64 per cent., and from 41 per cent. to 60 per cent., respectively.

It is customary in describing operations against mosquitoes to discuss the results in the most optimistic way. It is noticeable, however, that very rarely is any attempt made to measure the effect of the operations by accurate observations regarding a reduction in adult mosquitoes, nor, it is thought, has any such definite proof as a diminution in endemic index been attempted except in the operations summarised above. Such

statements as "malaria has lost its terrors for us," or, "all the natives remark that they are not nearly so much troubled by mosquitoes as they were," are, of course, incapable of being refuted, but, on the other hand, they afford no evidence of a reduction of either malaria or mosquitoes. Even apart from these considerations it is difficult to understand, in the face of the results obtained at Mian Mir, the easy success of some reported anti-mosquito operations. The present operations, so far as destruction of larvæ was concerned, were eminently successful. Moreover, a reduction for a time of the endemic index of a bazaar and of the admission rate of the troops was apparently achieved. Nevertheless, taking into consideration the length of time during which the operations have been carried on, the fact that they were conducted under favourable conditions, and that they were controlled during both the years of observation by medical officers possessing expert knowledge of the subject, the success attained scarcely warrants the conclusion that anti-mosquito operations would be an efficient practicable measure in every cantonment. Moreover, it must be remembered that, even had the operations been more successful, about one-quarter only of the whole cantonment of Mian Mir was taken in hand, and that to deal with this portion alone required all the energies of a medical officer wholly devoted to the task. On the whole, therefore, it would appear that the results of the present experiment were distinctly against the employment of anti-mosquito measures as a practical means of combating malaria in such a cantonment as Mian Mir.

As regards the administration of quinine to troops, the experiments clearly showed that the administration of 15 grains of quinine on two successive days weekly was a most powerful means of combating malaria. At the same time, however, they demonstated the great difficulty of applying this means of prophylaxis to large bodies of men, and the necessity, which has been so often emphasised in these pages, of ensuring that the quinine is given under the immediate supervision of a medical officer. It may even be said that the difference in the results of accurate experiment and of administration as ordinarily practised was so marked, that it appears doubtful whether, with the means of supervision at present available, this measure could be applied with much benefit as a routine one to troops.*

The first edition of 5,000 copies of the pamphlet on the causation and prevention of malarial fevers, which was drawn up by Captain James for the use of Assistant Surgeons and others, was soon exhausted. In the preparation of a second edition, the text has been revised, illustrations have been added, and the scope of the work has been enlarged so as to make it an easy introduction to the study of malaria. The new edition was issued in November, 1903, and has already been widely circulated. In connection with this subject attention may also be drawn to the books entitled "The Practical Study of Malaria," by Dr. J. W. W. Stephens and Lieutenant S. R. Christophers, I.M.S., and "Laboratory Studies in Tropical Medicine," by Dr. Daniels of the Colonial Medical Service.

Malta fever.—In 1897 Professor Wright directed attention to the possibility that Mediterranean or undulant fever might be prevalent in India as well as in the Mediterranean basin. His surmise was based upon the fact that in the cases of ten soldiers who had been invalided from India he had obtained serum reactions with the *Micrococcus melitensis*. Six of the men, however, had previously served in Mediterranean stations, and except in one of the remaining four cases the highest dilution in which the sero-sedimentation effect was obtained upon the micrococcus was 1 : 200. Captain Lamb, I.M.S., afterwards published an account of several cases of anomalous fever occurring among Europeans in Bombay, in which serum reactions were obtained with the micrococcus, and Lieutenant Greig, I.M.S., published an account of three cases of fever occurring among natives in the Swat valley, in the first of which a sero-sedimentation reaction was obtained in a dilution of 1 : 120, in the second in a dilution of 1 : 90, and in third in a dilution of 1 : 40.

That Malta fever should occur among European soldiers recently arrived from regions where the disease is endemic is perhaps to be expected, but whether this fever is indigenous in India and of common occurrence among natives cannot be said to be definitely known. If reported cases of the disease are to be accepted, it certainly would appear that Malta fever arising from local conditions is of frequent occurrence in India. A study of the histories of cases returned under this heading by medical officers

* Full particulars of the operations will be found in No. 6 of the "Scientific Memoirs" (New Series); first report of the anti-malarial operations at Mian Mir (1901–1903), by Captain S. P. James. I.M.S., and in the forthcoming second report by Lieutenant S. R. Christophers, I.M.S.

in charge of British and native troops and jails, however, throws some doubt on the accuracy of the diagnosis of Malta fever. Many of the cases have exhibited very few, if any, clinical symptoms of the disease and appear to have been returned as Malta fever on the strength of a positive serum reaction alone. It is not impossible that some of these diagnoses were based upon a mistaken valuation of the results of a serum test. It is, perhaps, unnecessary to point out that normal serum has the power of agglutinating most organisms to a certain extent, and that a positive result with a serum and an organism cannot be called specific unless the reaction occurs in sufficiently great dilution ; the so-called specific reaction is indeed merely a reaction at such dilutions as are impossible in the case of normal serum. It is sometimes forgotten, however, that not only is the agglutinating power of individual normal sera very variable, but that an organism by becoming attenuated in virulence, is rendered indefinitely susceptible to agglutination by normal serum. A sufficiently attenuated typhoid organism may from this cause give reactions readily with normal sera in dilutions of 1 : 100. In order to avoid all chance of this action of normal serum upon organisms possibly very susceptible, most observers have found it necessary in carrying out the test to adopt (1) a short time limit, (2) complete reaction, and (3) reaction at high dilutions, as the three essential requirements for accurate diagnosis. A reaction in dilution 1 : 80, for example, in the case of an organism so susceptible and liable to changes as the *Micrococcus melitensis* does not appear to be sufficiently high to be of undoubted specific nature, and until experiments have been made as to the susceptibility of such cultures of the micrococcus as are available in India to the sera of apparently healthy Europeans and natives, and to the sera of persons suffering from other diseases, it is impossible not to be sceptical regarding the correctness of some of the diagnoses of Malta fever based upon serum tests alone. At any rate it is extremely desirable that a more critical attitude should be taken up in the employment of serum diagnosis, for it is a significant fact that, although for more than five years Malta fever has been regarded as a fairly common disease of India, the micrococcus itself has not yet been isolated from any case.

Trypanosomiasis.—The recent discovery of parasites of the genus *Trypanosoma* in the blood of Europeans and natives in Africa has aroused considerable interest, and the Government of India, recognising the possibility that in this discovery might lie the clue to the causation of certain obscure diseases of India, deputed an officer of the Indian Medical Service to join the members of the Royal Society's Commission, who had proceeded to Uganda in February, 1903, to investigate the disease known as " sleeping sickness." Captain E. D. W. Greig, I.M.S., was selected for the duty, and joined Lieutenant-Colonel D. Bruce, F.R.S., R.A.M.C., and Dr. Nabarro, the Commissioners of the Society, at Entebbe in Uganda on the 25th of May.

There is evidence that observers in this country have not been slow to follow the lead of their *confrères* in Africa in recognising the importance of the new discovery. In several parts of India search has already been made for trypanosomes in the blood of man, but so far without success. As a result of the recent researches, however, further investigation of these parasites, both in men and animals in India, is likely to become more general, and in view of the fact that the literature bearing upon this subject is not everywhere available, a brief summary of the landmarks of our knowledge regarding trypanosomiasis may not be out of place here.

In November, 1843, Gruby described a protozoal parasite of the blood of the frog to which on account of its peculiar boring movements he gave the name *Trypanosoma sanguinis* (Gr. *trupanon*, an auger). Gluge had possibly observed the same parasite in 1842, and it was probably also identical with the *Amoeba rotatoria* observed by Mayer in July, 1843, and perhaps, with the *Undulina ranarum* described by Ray Lankester in 1871. The " vermicules " which were observed by Gros in 1845 in the blood of a field-mouse and by Chaussat in 1850 in the blood of rats (*Mus rattus*) were also probably of the nature of trypanosomes ; but it was not until the researches of Lewis in 1877 that the first accurate description of these parasites in the blood of warm-blooded animals was given. Lewis made his discovery of flagellated organisms in the blood of rats in July, 1877 during an examination of these animals in connection with an investition into spirillum fever at Bombay, and he afterwards found that 29 per cent. of the apparently healthy rats (*Mus decumanus* and *Mus rufescens*) examined by him at Calcutta, harboured the parasites. He found them also in the rats at Simla and other places in India, and Vandyke Carter found them in 12 per cent. of the rats examined at Bombay. The next discovery—truly, as Vandyke Carter said, an epoch-making one—was made by Veterinary Surgeon Griffith Evans, who in 1880 submitted a report on

"surra," as a newly-diagnosed disease very prevalent among horses in the stations of the North-West Frontier, and constantly associated with the presence of numerous organisms in the blood. Lewis regarded these organisms as very similar, if not identical, with the flagellated organisms discovered by him in the blood of rats. Evans showed by experiment that the surra parasites and disease were both communicable by inoculation to healthy horses and to dogs. In January 1885 Veterinary-Surgeon J. H. Steel, when investigating a hitherto unrecognised disease among the transport mules in British Burma, found it to be the same as the "surra" of the North-West Provinces, and showed further that the monkey was susceptible to this infection. Steel sent specimens of contaminated blood from mules, dogs, and monkeys to Vandyke Carter at Bombay, who came to the conclusion that morphologically the hæmatozoon of surra was identical with that of apparently healthy rats. In 1886 Cunningham also found parasites which he regarded as identical with those of Lewis, Steel, and Evans, in slides of blood from horses, mules, and ponies, suffering at Meerut from an epidemic disease which had come under the observation of Veterinary-Surgeon W. D. Gunn. Steel and Evans had conclusively shown that both the disease and the parasites of surra were readily communicable by inoculation to other animals, and Vandyke Carter had shown that it was very difficult, if not impossible, to communicate the rat parasites by inoculation to the dog, cat, horse or monkey. Out of 15 inoculation experiments carried out with contaminated rats' blood by him on these animals and on one other rat, in only one case (that of a monkey) was a positive result obtained, and in that case the parasites were present in the inoculated animal only on the 2nd and 3rd days after the experiment : they then disappeared and the animal remained perfectly well. In spite of these facts and in spite of the fact that the rats harbouring the parasites did not apparently suffer from any disease, Vandyke Carter as well as Lewis, Steel, and others, regarded the rat parasites as probably identical with those of "surra"—Vandyke Carter making the remark that India was the seat of a widespread and very serious equine disease, having for one of its characteristics a blood contamination seemingly identical with one largely prevalent among common rodents of the country.

In the meantime the attention of observers in Europe had been directed to the subject, and in 1881 Koch and v. Wittich discovered a parasite in the hamster which appeared at the time to be identical with the parasite of rats, but which Laveran and Mesnil now consider to be a distinct species. Kent in 1882 described the parasite of the rat under the name *Herpetomonas lewisi* and in 1886 Crookshank, who had found the parasites in 25 per cent. of the rats examined by him in London, regarded them as belonging to the genus *Trichomonas*. The parasites of rats were also studied by Danilewsky, Chalachnikow, and others. In 1894 Bruce discovered that the disease of horses and other animals in Africa called "nagana" is caused by a trypanosome very similar, if not identical, with that which causes "surra" in India, and that the disease is communicated from animal to animal by means of the tsetse-fly ; and in 1896 Rouget's discovery of an apparently new species of the genus *Trypanosoma* as the causative agent of the disease of horses called "dourine" or *mal du coît* added further interest to the subject In November 1896 Bruce sent a dog infected with "nagana" to England, which formed the starting point of the researches of Kanthack, Durham, and Blandford in London and Cambridge. Plimmer and Blandford afterwards continued the researches in London and published their results in 1899. In the same and the next year Rabinowitsch and Kempner and Wasilewski and Senn published accounts of their researches on rat trypanosomes, which were followed in 1901 and later years by a very important series of observations on parasites of this genus by Laveran and Mesnil. For some time it was thought that the *T. lewisi* of rats and the *T. evansi* of "surra" were identical, but Koch, Rabinowitsch and Kempner, and Laveran and Mesnil have shown that the *T. lewisi* is peculiar to rats. Even the hamster which, as mentioned above, is frequently infected with a trypanosome very closely allied to *T. lewisi*, is refractory to this parasite. Morphologically also the two parasites present differences by which, according to Laveran and Mesnil, they can be distinguished. Koch, Nocard, and others have expressed the opinion that the parasite of surra (*T. evansi*) and that of nagana (*T. brucei*) are identical. In spite of the voluminous memoirs of Lingard on surra, the structure of this parasite is still very incompletely known, so that a complete morphological comparison of the parasites is not possible. The same animals are susceptible to the two diseases and in the horse the course of the two diseases is similar. In the case of experimental inoculation also the incubation period of the two diseases is the same. On the other hand, whilst cattle, according to Bruce, nearly always die of nagana, they usually recover from surra. In Zululand Bruce also came to the conclusion that the tsetse-fly was the only one capable of carrying nagana. This would point to the fact that nagana is distinct from surra, for, according to Austen, the tsetse-fly occurs only in Africa ;

and the observation of Captain Rogers, I.M.S., that surra is carried from animal to animal by means of horse-flies, probably adds further evidence of the distinctness of the two diseases, instead of, as he suggests, pointing to their being identical. The question cannot, however, be decided definitely until the experiment of immunizing animals against the parasites of surra and then ascertaining if they are susceptible to an infection with the parasites of nagana has been made. A third important disease of animals associated with the presence of trypanosomes in the blood affects horses in South America and is known as *mal de caderas*. The discovery of the parasite of this disease was made by Elmassian in 1901, and confirmed by Voges in the same year. Morphologically the parasite resembles very closely those of surra and nagana, and though Lignières and Elmassian and Migone were unable to detect the presence of a "centrosome" at the point of insertion of the flagellum, Laveran and Mesnil succeeded in doing so. As in nagana and surra all animals experimented with up to the present have been found to be susceptible to the disease, but Laveran and Mesnil have shown that a goat and sheep, which had recovered from nagana, and which, therefore, possessed an immunity against this affection, readily contracted an infection with the parasite of *mal de caderas*. The converse experiment of infecting an animal which had recovered from *mal de caderas* with the trypanosome of nagana was successfully made by Lignières, so that the trypanosome of this disease would appear to be quite distinct from that of nagana. The last disease of animals caused by trypanosomes, to which it is needful to refer here, is that known as "dourine" or *mal du coît*, a disease of horses which has been carefully studied in India by Veterinary-Major Pease. It is probable that the parasite of this disease was first seen by Chauvrat in 1892, but he regarded the case as one of surra, and the merit of having first discovered the parasite is usually ascribed to Rouget, who in 1896 observed it in the case of a horse suffering from the disease. Although morphologically resembling the parasties of surra and nagana, the parasite of dourine [*T. equiperdum* (Doflein) or *T. rougeti* (Laveran and Mesnil)] is now regarded as quite distinct from these as well as from the parasite of *mal de caderas*. The only known way by which dourine is naturally communicated is by coitus* ; the course of the disease in animals is different from that of nagana or surra ; its duration is generally some months ; the parasite is very rare in the blood ; and above all, many animals such as monkeys, guinea-pigs, goats, sheep and cattle, which are susceptible to nagana are quite insusceptible to dourine. Nocard also has shown that dogs immunized against dourine succumbed to nagana in 11–14 days, and Lignières has shown that dogs immunized against dourine succumbed to an infection with *mal de caderas*, so that the parasite would appear to be certainly distinct.

It will suffice to conclude this *résumé* with a brief account of the recent discoveries relating to trypanosoma disease in man. Nepveu (in 1891) appears to have been the first to recognise trypanosomes in the blood of man, but although he maintained that these parasites must be reckoned with as a factor in tropical pathology, little attention was directed to his discovery, and it remained for Dutton to bring the subject into prominence by his recognition and description of a parasite found by Forde in 1902 in the blood of a European in Gambia. Dutton also found the parasites in the blood of an apparently healthy native child in the same district, and later he and Todd found six more cases of trypanosomiasis among 1,000 individuals whose blood they examined. Manson and Daniels added another case in the person of a European from the Congo, and the occurrence of cases in other parts of Africa was reported by Le Moal, Brumpt and Broeden. In November 1902 Castellani discovered that the infection occurred among the natives of Uganda, and made the important observation that in some cases of sleeping sickness trypanosomes were to be found in the cerebro-spinal fluid. Out of 34 cases of sleeping sickness he found trypanosomes in the cerebro-spinal fluid in 20. His discovery was confirmed by Bruce, who, with Nabarro, had been sent out as a Commission by the Royal Society to make further investigations into this disease. Up to the end of May 1903 Bruce and Nabarro had studied 40 cases of sleeping sickness and had found trypanosomes in the cerebro-spinal fluid in all, and in the blood in 15 out of 16. Later the blood of a number of inhabitants of sleeping sickness and non-sleeping sickness areas was examined by the Commission. Out of 80 natives from a sleeping-sickness area, 23 or 28·7 per cent. were found to have trypanosomes in their blood, while in the examinations of 117 natives from areas where sleeping sickness was unknown not a single trypanosome was found. The Commissioners report that the parasites were never found in the cerebro-spinal fluid of persons not suffering from sleeping sickness, and that in cases of "trypanosoma fever" —the disease described by Dutton—they could only be found in the blood. Two species

---

* *See*, however, Rabinowitsch and Kempner in C. B. XXXIV, No. 8, page 808.

of monkeys, as well as (to a less extent) rats and dogs, were found to be susceptible to the trypanosomes from cases of sleeping sickness and of trypanosoma fever, and in later experiments it was also found that monkeys inoculated with cerebro-spinal fluid from sleeping-sickness patients or with blood from cases of trypanosoma fever died with symptoms of sleeping sickness ; and *post-mortem* their brains presented the typical appearance met with in human beings dead of that disease. From the analogy with nagana it was suspected that in human trypanosomiasis a like mode of infection took place, and it was shown by experiment that a species of tsetse-fly (*Glossina palpalis*, Austen) after biting human beings suffering from trypanosomiasis could convey the disease to monkeys. It was also shown by an extensive series of observations that the distribution of sleeping sickness and of *Glossina palpalis* exactly correspond. From a letter recently received from Captain Greig it appears that morphologically and as regards their effects when injected into animals the trypanosome of the blood and that of the cerebro-spinal fluid are identical ; and five cases of trypanosoma fever were under observation with a view to ascertain whether the trypanosome present in the blood would ultimately be found in the cerebro-spinal fluid, and whether the cases would develop sleeping sickness. At the time of writing, in two of the cases the trypanosome had been found in the cerebro-spinal fluid, and in one of these cases early symptoms of sleeping sickness were apparently present. If the further investigations of the Commission confirm their previous work it may be concluded that, in all probability, sleeping sickness is caused by the entrance into the blood and thence into the cerebro-spinal fluid of a species of trypanosome (probably that described by Dutton) which is transmitted from the sick to the healthy by a species of tsetse-fly (*Glossina palpalis*) and by it alone.*

An important parasite.—In May, 1903, Major W. B. Leishman, R.A.M.C., reported the discovery of certain parasitic bodies, which, he suggested, might possibly be the remains of trypanosomes, in films taken *post-mortem* from the spleen of a soldier who had died from an anomalous type of fever apparently contracted in Dum Dum, near Calcutta. In the following July, Captain Donovan, I.M.S., announced that similar bodies had been found by him in blood obtained by splenic puncture from a number of patients suffering from enlargement of the spleen in Madras ; and in January 1904, Professor Marchand and Dr. Ledingham published an account of a case in which similar bodies had been found in sections of the spleen, liver, and bone marrow, obtained at the *post-mortem* examination of the body of a soldier who had apparently contracted his fatal illness in China. The parasites discovered by Captain Donovan were studied in films by Major Ross, I.M.S., and by Professors Laveran and Mesnil, and a difference of opinion exists between these authorities as to the exact zoological position of the parasites, for while Major Ross considers that they should be classed in an entirely new genus, Professors Laveran and Mesnil regard them as belonging to the genus *Piroplasma*. Further interest has been added to the subject by the publication of a paper by Dr. J. H. Wright, of Boston, in which a description is given of certain parasitic bodies obtained from a specimen of "Delhi Sore." These bodies were discovered by Surgeon-Major D. D. Cunningham, I.M.S., as long ago as 1885, and, so far as can be judged from the description and the excellent photographs in Dr. Wright's paper, they may be identical with the bodies discovered by Major Leishman.

As it appeared probable that Captain Donovan's discovery of the parasites in cases of enlargement of the spleen in Madras was likely to be of importance, Lieutenant Christophers, I.M.S., who was at that time on special duty in connection with malaria, was directed to proceed to Madras to investigate their nature. In a preliminary report,

---

* It would occupy too much space to give a complete bibliography of the subject here. Such a bibilography is contained in the article by Doflein and Prowazek on *Die pathogenen Protozoen* in Kolle and Wassarmann's *Handbuch der pathogenen Mikroorganizmen*. The following articles, which are easily accessible, may, however, be mentioned :—T. R. Lewis in S. C. I. for 1877 and in the Quarterly Journal of Microscopical Science, 1884, Vol. XXIV., pages 357 to 369 ; Vandyke Carter in Sc. Mem. by Med. Officers of the Army of India, Part III., 1887 ; Cunningham in the same ; Crookshank in the Journal of R. Microscop. Soc., Nov. 1886, page 913 ; Laveran and Mesnil in A.P. XV., 1901, page 673, and in A.P. XVI., 1902, page 1 ; Rouget in A.P.X., 1896, page 716. On page 189 of this volume will also be found an analysis of Bruce's preliminary report on nagana ; Elmassian and Migone in A. P. XVII., 1903, page 241. This article as well as others by Lignières, Sivori, and others, are reviewed in B.I.P. No. 1, pages 365–367. The literature regarding human trypanosomiasis is contained in the current numbers of the medical journals. A good summary and a complete bibliography since 1898 will be found in an article by Rabinowitsch and Kempner in C.B. XXXIV., No. 8. An article on sleeping sickness by Castellani in C.B. XXXV., No. 1, should also be consulted. Bruce and Nabarro's preliminary report is contained in the Royal Society's Reports of the Sleeping Sickness Commission, No. 2, August 1903, and the further report by Bruce, Nabarro and Greig in No. IV. of the same Reports, November 1903. The *résumé* in the text was written before the appearance of the paper by Schaudinn entitled "Generations und Wirtswechsel bei *Trypanosoma* und *Spirochæte*." Arbeiten aus dem Kaiserlichen Gesundheitsamte. Vol. XX., page 387.

Lieutenant Christophers gives a description of the parasites and of the clinical features and post mortem appearances of the cases in which they were found. It seems that they are essentially different from the malaria parasite and from parasites of the genus *Piroplasma*, in that they are never found in the red blood corpuscles. A most striking feature is their presence in large numbers in the leucocytes of the spleen and liver, and in addition to the usual kinds of leucocytes present in these organs there are found in cases of the disease numerous large cells resembling macrophages, packed with parasites. Some of these cells are very large and may contain as many as 250 parasites. Besides the liver and spleen, the parasites were found by Dr. Christophers in the red bone marrow, in the submucosa of the large intestine, in petechiæ from the arachnoid, in blood from the liver and portal vein, and in small numbers in blood from the spleen. They were never found in peripheral blood.

The bodies exhibit a remarkable uniformity in size and appearance. The majority are approximately circular in outline and about 2·5 micromillimetres in diameter, but some are larger and very much resemble a cockle-shell in shape. In stained specimens they are seen to possess two chromatin masses—a small one usually rod-shaped, and a large one which may be bilobed, or heart-shaped, or formed of two oval masses lying in contact.

An important discovery was the fact that ulceration of the large intestine is apparently a marked feature in all advanced cases, and that this ulceration is apparently produced by a process analogous with that which brings about the ulceration in cases of Delhi boil, viz., by the deposition in the submucosa of granulation tissue, which, after destroying the crypts and surface epithelium, undergoes necrosis and forms ulcers reaching as deep as the muscular coats. The parasites were present in large numbers in the mucous membrane and submucous tissue in the vicinity of the ulcers.

The clinical features of the cases in which the parasites were found were extremely characteristic. The cardinal signs given by Dr. Christophers are :—(1) great enlargement of the spleen, (2) emaciation, (3) irregular pyrexia, and (4) abdominal symptoms. The pyrexia and course of the disease are quite uninfluenced by quinine. In advanced cases diarrhœa and a dysenteric condition with blood and mucus in the stools are a constant feature, and death from peritonitis due to perforation occurred in two out of the three fatal cases which are described in the report. It is well known that cases presenting these clinical features are very common in India, and Dr. Christophers has no hesitation in saying that the cases of infection with this newly found parasite which were seen by him in Madras are clinically identical with cases usually diagnosed as "malarial cachexia with enlarged spleen." If this be so, the parasite will no doubt be found to be very widely distributed in this country, and a great advance in our knowledge of the Indian fevers will have been made. Until further work on the parasite has been done, it is impossible to assign to it a definite zoological position, and premature conclusions are much to be deprecated. That it does not belong to the genus *Piroplasma* appears to be amply proved by Dr. Christophers in his report, and at the present time the suggestion put forward by him, and independently by Wright, that the organisms seen in the characteristic large cells represent the spores of a *microsporidian* seems probably correct.

Pasteur Institute of India.—During the year ending 8th August, 1903, 584 patients were treated at the Pasteur Institute, Kasauli, as compared with 543 treated during the previous year. Of this number 269 were Europeans (207 men, 20 women, and 42 children), and 315 natives (255 men, 10 women, and 50 children).

The following tables exhibit the results among Europeans and natives respectively.

The tables do not include ten persons who presented themselves for treatment but were found not to require it, nor do they include four patients (three natives and one European) who developed hydrophobia during treatment, and two persons (both natives) who were attacked within 14 days after the completion of treatment.

On comparing the tables it will be seen that better results were obtained in the treatment of Europeans than of natives. The reasons assigned by Lieutenant-Colonel Semple for this were that the Europeans were less severely bitten, had their wounds more promptly and better attended to immediately after the bites, with few exceptions came earlier for treatment, were a healthier and stronger lot of people, and better fed before, during, and after treatment, and on this account were in a better position to become more highly immunised, and to offer more resistance to infection.

The small number of patients shown in class A (bitten by animals proved rabid) is attributed to the faulty condition in which the samples of brain or spinal cord from the animals which inflicted the bites were sent for diagnosis. Lieutenant-Colonel Semple

points out that for diagnostic purposes it is only necessary to send a small portion of either the brain, cord, or medulla in a small bottle of sterile neutral glycerine, and to do so as aseptically as circumstances will permit. Any other method of sending a sample of a "suspected rabid brain or cord" for diagnosis only results in putrefaction or destruction of the virus.

In badly bitten and late cases an anti-rabic serum, prepared at the Institute, has been used with good results as a preliminary to the usual methods of treatment. In these selected cases a dose of serum is given on the first day, after which the usual methods of treatment are carried out, commencing the day after the serum. The rationale of the method of treatment by anti-rabic serum is given by Lieutenant-Colonel Semple in the following words :—

> "In badly bitten and late cases the object of treatment is to confer a high degree of immunity as soon as we possibly can. An active immunity, such as is acquired by a patient who undergoes the usual method of treatment, takes a considerable time to accomplish ; but a passive immunity, such as is conveyed by using the serum of another animal which has been highly immunised, can be acquired very quickly. This state of passive immunity does not, however, last for long. It is easily acquired, but soon wears off again. My object in using the serum at all is to give badly bitten and late cases the benefits of this passive immunity, until they can be trained to acquire the more durable active immunity, which can only be acquired by undergoing a series of inoculations with rabid virus. In other words, the patient gets the benefit of the immune bodies contained in the anti-rabic serum given him, until he can be trained to prepare his own immune bodies."

In addition to the anti-rabic treatment, much general bacteriological work was carried out at the laboratory in connection with the diagnosis of enteric fever, Malta fever, malarial fever, plague, tubercle, diphtheria, &c.

One thousand nine hundred and twenty-five doses of typhoid vaccine were prepared and sent out between the 9th August 1902, and the end of January 1903.

Antivenene was prepared, and 1,020 bottles, each containing 15 c.c., were distributed for use all over India. "In a short time it will be possible to meet all demands in India for this serum."

Anthrax vaccine was prepared, and 560 doses sent out to applicants where outbreaks of anthrax had taken place. The preparation of diphtheria antitoxin and of tetanus antitoxin has also been commenced.

Scientific Memoirs.—Seven numbers of the new series of Scientific Memoirs by officers of the Medical and Sanitary Departments of the Government of India have been published and widely distributed, not only in India and in Great Britain, but to most of the universities and more important scientific libraries throughout the world. The two most recent numbers were the "First report of the anti-malarial operations at Mian Mir, 1901—1903," by Captain S. P. James, I.M.S., and "Some observations on the poison of the banded krait (*Bungarus fasciatus*)," by Captain G. Lamb, I.M.S. Early numbers will contain the preliminary report by Lieutenant Christophers, I.M.S., on a parasite found in persons suffering from enlargement of the spleen in India, and by the same officer, the "Second report of the anti-malarial operations at Mian Mir," which is a continuation of the first report already mentioned.

18309

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1902.

(*Lieutenant-Colonel W. G. King, C.I.E., I.M.S.*)

General Population.

The population under registration during the year was 36,331,518,* against 38,252,900* of the Census population of the Presidency, and 38,744,900* of the estimated population for the period. As usual in a fairly prosperous year, emigration declined; there being a total of 58,782 less departures than in the previous year. Immigrants exceeded emigrants by 47,505.

It has repeatedly been pointed out in the Annual Reports of this office that the necessity for including statistics received from areas under Zamindars, whose village officials are not subject to the same grade of discipline as those under Collectors, vitiated results. Government therefore directed that Collectors should supply two sets of monthly statistical returns, in one of which zamindari areas should be eliminated, so as to test this fact. The result has been to show that parts of districts under revenue control afford decidedly better registration results than those under zamindari rule.

Births in Districts.—A total of 1,023,146 births was registered during the year. This represents a birth-rate of 28·2 per 1,000, or an improvement of 3·1 per 1,000 compared with last year. This increase must, in chief part, be ascribed to the influence of cheaper food-grains, as although doubtless year by year increased attention is being paid to registration, this could have had but little effect, seeing that, although the birth-rate has improved, it has not yet so far recovered from the depressing influences (detailed in my preceding report) to which it had been subjected as to reach even the average figures for the five preceding years. Indeed, it cannot be accepted that full results can be exhibited until the statistics for 1903 are gathered. It will then be of interest to ascertain how far those districts that chiefly suffered from high prices have undergone rapid increase of population, which is the natural sequence of a temporary depression of the nature indicated. In the meantime, it is noteworthy that of the districts stated in last year's report to have had particularly poor birth-rates, namely, Chingleput, North Arcot, Kistna, Madras and Kurnool, there is in each case exhibited a greater rate of increase than in other districts, if Madras be excepted. Both in Madras and Anantapur, a falling off from last year's poor birth-rate has occurred. As to Anantapur, the difference is small enough to be compatible with less careful registration by village heads, probably owing to the additional work in connection with plague. As to Madras, it may be accepted that no relaxation of registration efforts has occurred, and that consequently the still unarrested decline of births may be due to disturbance of the already disproportionate population of males and females during the continuance of high prices, which was not sufficiently recovered from during the short period available in the year under review. However this may be, it is necessary that the possibility of relaxation of vigilance as to registration in the City of Madras be considered by the authorities concerned.

Deaths in Districts.—The death-rate for the districts as a whole in 1902 was 20·2 per 1,000, against 21·3 per 1,000 in 1901. That the decline in the death-rate is not due to increasing imperfection in registration may be accepted, when it is remembered that the birth-rate obtained from statistics gathered from the same agency has shown a marked increase. The diminished rate is chiefly accounted for under cholera. If the epidemic diseases cholera, small-pox and plague be eliminated from the statistics of both years, the

* Inclusive of Europeans and Eurasians.

death-rate from ordinary causes was 18·4 per 1,000 in 1902—the same rate as obtained in 1901. Whilst the total average rate for the Presidency shows the decline stated, the following six districts exhibit rates above those of the preceding year :—Bellary (8·9), Madura (5·4), The Nilgiris (5·6), South Arcot (1·9), Tanjore (1·3), and Tinnevelly (3·5). In the last two districts the increased mortality was due to cholera, and in the first to plague.

Births in Municipalities.—There are now 61 towns under municipal rule in this Presidency, where compulsory registration of births and deaths is enforced by the employment of special staffs. These towns contain an aggregate population of 2,422,121. The total births for the year being 78,599, the birth-rate was 32·7 per 1,000—an advance of 0·1 per 1,000 on the previous years. It will be noted, in reference to prices of food-grains, that the fluctuation in birth-rates exhibited by the rural population is not evident amongst the inhabitants of the municipal towns which, as suggested by me last year, will go to show that the past pressure of prices was chiefly felt by the lowest class of the agricultural population. The marked decrease in the Bellary rate is ascribable to desertion of large portions of the town during the existence of plague, and the same reason is applicable to Adóni, Walajapet, and Mangalore. Seeing that, as established by Messrs. Stokes, Hardy, and Stuart (Madras Census Commissioners of different periods), the normal birth-rate in this Presidency must be somewhere between 42·45, 53, and 52 per 1,000, the decline of the birth-rate, when compared with the previous year (in which it had by no means approached the normal) of more than 2 per 1,000 in the case of Madura, Ongole, Karúr, Chidambaram, Kumbakónam, Máyavaram, Negapatam, Tinnevelly, and Palamcottah, must be the result of absence of active supervision of the collection of vital statistics by the respective councils. Several municipal councils persist in employing too few men for the work of registration. They are frequently very badly paid and badly educated. The rate of 25·4 per 1,000 for Negapatam is manifestly incorrect, even when compared with the poor results of other towns in the same district, and notwithstanding a slight intercensal decrease of population as ascertained from the census of 1901.

Deaths in Municipalities.—The total death-rate of municipal towns shows a decrease of 2·9 per 1,000, when compared with the past year. The decline is chiefly under the head of cholera and fevers. Excepting plague-infected towns, Madras City heads the list of mortality with a rate of 42·4 per 1,000. This, with a birth-rate of but 34·9 per 1,000, shows that this town depends for its existence upon immigrants. The rate, however, is a considerable improvement upon that of 55·5 at which it stood last year. The significance of recorded rates quoted for the Madras City can, however, only be correctly appreciated by remembering that the proportion of males and females and of persons at "useful ages" differs from that obtaining in the average municipality of the mufassal. Thus, I showed some time back (Administration Report for 1893) that a recorded death-rate for Madras of 40·47 per 1,000 really meant, when corrected for age and constitution of population according to the standard obtained from 23 fairly representative municipalities, a rate of 43·45 per 1,000.

The heavy death-rates recorded for Bellary, Adóni, Vániyambádi, and Mangalore are due to the existence of plague, and those of Ellore, Tuticorin, and Tinnevelly to the presence of cholera during the year. The satisfactory decline of the death-rates of Cochin and Berhampur, when compared with the preceding year, followed the absence of cholera. In regard to Vániyambádi, it will be noticed that, whilst its death-rate is 128·9, the birth-rate is recorded as 63·1. This town is largely composed of Muhammadans, who are much married and maintain considerable zenanas. The rate may therefore be correct, but, if so, it is singular that the partial evacuation of the town two years in succession owing to plague has not exhibited more influence. At any rate, the veracity of the statistics will be specially enquired into.

The infantile death-rate in municipal areas was 233·3 per 1,000 of recorded births, against 237·3 during the previous year. The former figure represents a decline of 4 per 1,000, which must be regarded as satisfactory, and is probably the response to removal of the indirect influences of high prices of food-grains. Still, the heavy death-rate contrasts markedly with that found in rural areas, namely, 168 per 1,000. As both rates are reckoned upon total registered births, there is no more likelihood of mistakes as to one than the other, and it will be observed the proportion of male to female deaths, namely, 100 to 90·2 in rural areas and 90·16 in municipal areas, shows no very special difference. There is thus room to believe that both rates fairly represent facts as found. According to a standard formed by me from analysis of statistics of 23 fairly healthy

towns, it may be taken that the death-rate of infants ought not, under average insanitary conditions of this Presidency, to exceed 176·25 per 1,000 of births. Consequently, there should be no difference of opinion that in towns exhibiting a death-rate of infants of over 250 per 1,000, there is some specially inimical influence at work. These are Guntúr, Bezwada, Ongole, Madras, Chidambaram, Negapatam, Madura, Tuticorin, Tirupati, Coimbatore, and Karúr.

In regard to Guntúr, the death-rate of infants has long been persistently high. On making enquiries as to the causation, I have hitherto received no satisfactory reply. The cause of death as registered in Guntúr is largely "Convulsions,"* but, as this is usually the heading under which deaths of infants are placed by lay registrars, this nomenclature conveys no information. Sanitary enquiry in such a matter must be preceded by a collection of medical facts, so as to secure some guidance as to the direction the enquiry should take. Arrangements will be made for a special investigation of this nature. In regard to other towns having this heavy rate, the majority possess high sub-soil water levels, unusually foul soils, and are overcrowded—all well-recognized factors influencing the infantile death-rate. Much of the death-rate is, of course, due to ignorance of domestic hygiene and nursing, and I am therefore glad to be able to state that at least one member of the educational department (Mrs. Brander, Inspectress of Schools) is making a speciality of the spread of knowledge on such matters by means of publications. That Dindigul should have an infantile death-rate of 89·6 is certainly not due to particular regard of sanitation by the Municipal Council, but to the more prosaic fact of absence of care as to registration.

So far as age at death is concerned statistics show that from 5 to 9, and 10 to 14, there is little difference in the death-rate of sexes, but that the influence of child-bearing establishes itself at the early age of 15 to 19 ; as might be expected in this country, having regard to nature of marriage customs.

Chief Diseases.

Cholera.—A total of 29,769 deaths have occurred from cholera. This represents 4·1 per cent. of the total mortality of the Presidency and a rate of 0·8 per 1000 of the population. 15,782 of these deaths were of males and 13,987 of females, a disproportion that would seem to indicate a special tendency for the male to contract cholera. When, however, the rate is applied to the respective populations of the sexes, it is found that the incidence is but 0·9 in the case of males and 0·8 in the case of females. The same line of reasoning occasionally leads to the belief that adults are more liable to be affected with cholera than the very old or the very young. But statistics scrutinized by me some time back show that in this Presidency, if the incidence be calculated upon, the populations of the respective ages, all ages are practically equally liable to attack—not even excepting infants of one year of age, who it must be remembered are generally fed with little hygienic care.

In regard to the incidence upon various districts, as usual, the statistics show that it is greater during the period of the monsoon which chiefly affects the district concerned. Thus, during the year in the south-west monsoon districts the incidence during that monsoon upon the population was 0·36 per 1000, and during the north-east monsoon was but 0·11 per 1000 ; whereas, in the north-west monsoon districts, the incidence during that monsoon was 0·17 per 1000, and during the south-west monsoon only 0·14 per 1000.

The so-called municipal cholera rules (Government Order No. 1536 M., dated 9th September, 1896) adopted by 24 municipalities, require that directly a town is "imminently threatened" with cholera, it should be warned, and that a definite staff should be added to the permanent staff for observation purposes, and if a town be actually attacked that to this be added a preventive staff. In the remaining municipalities, although the rules are not compulsory, no opportunity is lost by this office to impress them with the necessity of following the rules, as far as their funds will permit. Practically, therefore, the difference between two sets of municipal towns lies between the more and less complete adoption of the rules. Nevertheless this year, the difference of incidence of cholera although small is in favour—the mortality being ·1 per 1000 less —of those adopting the rules as a compulsory measure. During the year, the towns of Chidambaram, Cuddalore, Tiruvannámalai and Ellore, representing an aggregate population of 122,715, were added to the list of those adopting the rules.

* Of children under ten years of age, Municipal Registrars show 7·3 per cent. of the total death as due to "Convulsions.

In rural areas so late as 12 years back, it was no uncommon matter to find that the total sanitary arrangement made to combat cholera by local authorities was the deputing of vaccinators—who, by some occult reasoning, were regarded as possessed of sanitary or medical abilities, for the purpose of distributing cholera pills. Further back, I remember as Special Sanitary Officer of the Town of Madras during the epidemic of 1882, finding that disinfection meant distribution of sticks of sulphur to peons, who handed them to the owners of infected houses, who duly burnt them in their verandahs. Now-a-days in rural areas Certificated Sanitary Inspectors look to such matters and slowly—very slowly—synchronously with the dawning belief that sanitation may not deal solely with fads—these men are displacing untrained Conservancy Overseers, or Hospital Assistants who are erroneously expected to medically treat patients, and yet rush from village to village to tend sanitary matters. Moreover, considerable attention has been paid to water-supply in the larger towns, and some slight advance has been made in the same respect in rural areas. Can then the effect of such efforts be measured in figures? Admitting at once that epidemics of cholera in one decade might be more virulent than in another and therefore leaving the figures open to question, I would state that an improvement as to less incidence would seem to be exhibited by the fact that in the decades ending 1882 and 1892, the incidence of cholera was 2·7 and 2·7 respectively, but in that ending 1902, it was 2·0. The saving of life in the third decade would therefore amount to 258,756.

In respect to the efficacy of treatment by permanganate of potash of waters supposed to be contaminated with the cholera microbe, the opinions of District Medical and Sanitary Officers still remain much divided. Acting on the suggestion of the Army Sanitary Commission, by order of Government, I circulated to all District Medical and Sanitary Officers directions for the gathering of specimens of such waters for the purpose of being bacteriologically examined by me, in reference to the possible presence of cholera microbes in a living condition, before and after treatment of the water by permanganate of potash. Although this was issued in November, 1902, no specimens of contaminated water have yet reached me for examination.

Small-pox.—The incidence of small-pox on the population of the whole Presidency was the same as in the former year, namely, ·7 per 1000. In the districts of Malabar, North Arcot, and Bellary, the incidence was 2, 1·2, and 1·1 per 1,000, respectively. In the case of the district of Malabar, there can be no doubt that much attention is still required to the prophylactic operation of vaccination, and various efforts have of late years been made in this direction. The advance unfortunately must be slow, as Moplahs are not yet convinced that this precautionary measure of vaccination is not an attempt to cheat fate. But that advance has been made is evident from perusal of the following figures, showing the annual death-rates per 1,000 under the head of small-pox during the last ten years :—

1892...	4·4	1897...	0·01
1893...	4·6	1898...	0·04
1894...	1·3	1899...	0·05
1895...	0·03	1900...	0·2
1896...	0·1	1901...	0·8

In regard to municipalities, the total incidence upon the population was 0·8 per 1,000, against 0·6 per 1,000 of the previous year. Of the total of 2,041 cases, no less than 1,043 were contributed by three Malabar municipalities, namely, Calicut (667), Cochin (100), and Cannanore (276). In municipalities, the average age incidence under one year was 2·7 per 1,000, and between the ages of 1 and 10, 0·69 per 1,000; whereas, in rural areas, it was 8·1 and 0·7, respectively, showing the better protection obtained with the compulsion used in municipalities, and the folly in both areas of delaying vaccination till the child is six months old.

Compulsory clauses as to vaccination of the Local Fund Act were extended to 118 unions during the year. In the present state of organisation of the vaccination staff for the Presidency,* it is, however, not possible for full advantage to be taken of compulsion in these areas. During the year, the Inspector-General of Prisons forwarded an interesting communication showing steady decrease in the number of prisoners arriving at jails "unprotected," namely, 23·9 per cent., 21·7 per cent., and 13·9 per cent., respectively, in the years 1899, 1900, and 1901. As the figures concern average representatives of the uneducated classes of the community, the extent to which protection exists amongst adults may be thus fairly well gauged. Taking successive

* Government contemplates reorganisation.

decades into account, as in the case of cholera, it is found that the very small expenditure on the Vaccination Department is justified by the following figures:—In the decade ending 1882, the small-pox mortality was 1·9 per 1,000; in that ending 1892, 1·4; and in that ending 1902, 0·3. The saving of life during the last two decades has amounted, therefore, to 572,980.

Respiratory Diseases.—Under this heading are grouped figures that doubtless by no means represent even an approach to truth, as the capacity of ordinary village officials to ascertain whether fever arises from an affection of the chest must be very little. What for some years probably will be gathered are instances of asthma, chronic bronchitis and phthisis, whilst acute affections of the pleura and pneumonia will be, as heretofore, placed under "fevers." Nevertheless, an attempt at differentiation is advisable, and should be persevered with. As reported by districts, the total deaths from respiratory diseases amounted to 0·1 per 1,000 of the population. There was nothing to indicate that the presence of plague induced registration (with reference to pneumonic plague) under "respiratory diseases." As ascertained, the mortality during 1902 under this head in municipalities was 1·4 per 1,000.

Plague.—During the year 10,795 deaths from plague were registered. 10,770 of these occurred in the districts of Anantapur (89), Bellary (7,354), Coimbatore (496), Kurnool (56), North Arcot (114), Salem (1,668), and South Canara (993), parts of which were indigenously affected. The territory under the Government of Mysore continued to form a special danger to this Presidency, in that beyond measures in the cities of Mysore and Bangalore very little attempt at organisation for checking the spread of the disease exists in that area. Some indication that the Mysore Government might arrange a mutual scheme for the protection of the respective frontier districts was perceptible, but nothing definite has been done up to date. So long as Madras territory is liable to be repeatedly invaded from an area where no organisation exists, the chances of successful resistance to the general spread over the whole Presidency are much lessened.

The municipal towns indigenously infected were Adóni, Bellary, Mangalore, Tiruppattúr, and Vániyambádi. The last-mentioned town has been a source of constant danger to surrounding areas, owing to the obstructiveness of the population.

No material change was made in the policy pursued by Government which may be said to be a system of surveillance, without detention, of all travellers passing from infected areas (whether these be within or without the Presidency) to uninfected areas so arranged that to whatever part of the Madras Presidency they journey, surveillance proceeds uninterruptedly for a period of ten days. As the people of this Presidency are generally better educated than elsewhere in India, this mild measure has been received in a sensible manner, and is fairly efficient. So far as can be judged, it has certainly been possible to detect the majority of imported cases, and numerous localities have been spared thereby from becoming indigenously infected. Where rural areas are "imminently threatened" by plague, special staffs composed of Certificated Sanitary Inspectors (or, when the supply of this class of men is insufficient, by those known as Temporary Sanitary Inspectors, who have been trained and have undergone examination solely with reference to plague work) are placed on duty, so as to strengthen the executive of the existing district staffs, and thus keep each inhabited area under systematic observation. These staffs are further strengthened by so-called preventive staffs, on attacks occurring in any area. In the municipal towns, also, special staffs for observation and prevention are organised. It has been the constant endeavour of Government to require local authorities to employ sufficient staffs to detect cases the moment they are imported and to take prompt means to prevent spread, instead of waiting till plague gets hold of an area and then making an effort.* Railway inspection has been used only where it is possible to protect a still uninfected area. As thus interpreted, railway inspection is efficacious. Thus, during the year, 176 cases of plague were withdrawn from the railway trains at Jalarpet, the point where cases from the Mysore territory are received.

If it be understood that by the means thus roughly indicated, it has been possible to trace the origin and progress of epidemics with greater accuracy than in areas where such

* Dr. R. Bruce Low, in his recent Report to the Local Government Board of England as to progress of plague and measures adopted in various countries, states, in reference to Madras,—"It is somewhat surprising to find that as yet, comparatively speaking, plague has hardly gained a foothold in this Presidency." I think this putting off of the, perhaps, ultimately inevitable defeat before advance of plague, may fairly be ascribed to the rigid adherence to this policy by the Madras Government, notwithstanding the receipt by it of much conflicting evidence and varying counsels.

means are not adopted, it may be accepted that experience in this Presidency shows that man causes the rat to suffer and not the rat man in the first place, that the area over which infected rats roam is usually small, and that recrudescence is by no means a natural feature of the disease, but a very natural result of apathy or too optimistic treatment of an indigenously infected area. Blind belief in this theory of recrudescence, when coupled with the theory of soil contamination, has trammelled all sanitary measures in India. If I am right, energetic application of sanitary measures during decline of the disease in the hot season is of much more value, and the possibility of stamping it out is much greater than usually held. Prolonged vitality of the plague microbe on the soil or its retention of vitality at any material depth, is probably a myth, and, if so, plague policy could be much modified. The amount of information placed at disposal of sanitarians by bacteriologists on this most important subject is meagre in the extreme. Members of the Indian Plague Commission commenced work in this connection, but had to leave the country before it was complete. I am perfectly aware of the difficulties presented to the bacteriologist in working in soil with the plague microbe, but a definite enquiry on lines required by the sanitarian would be worth many lakhs of rupees to the country, and it would be well worth while offering bacteriologists a substantial honorarium for the best investigation on the subject.

Fevers.—The mortality under the head of fevers was in districts 7·7 per 1000 against 7·9, and in municipalities 6·7 against 8·2 in the previous year. The mortality in the Madras town decreased from 18·3 to 14·7 per 1000, which figure however left it possessed of the highest rate in urban areas in the Presidency; the next in order being Kurnool and Nandyal—both notoriously malarious towns. In the absence of registration supported by medical diagnosis, it is, of course, impossible to ascertain what proportion of fevers in Madras town are due to malaria or to typhoid, and other possibly unnamed fevers. But that fevers of a truly malarial character exist in Madras has been long established, although Captain James, I.M.S., has shown that these are not of so severe a type as was perhaps imagined. The question of malaria in Cuddapah has long been under discussion, and measures towards improvement by relief of surface and sub-soil drainage have frequently been considered. The Council is at present discussing the question of limiting the wet cultivation. This undoubtedly acted beneficially in the case of Kurnool, where the municipality under my advice, in 1881, secured a zone of one mile radius from the town free of wet cultivation. Much abatement of fever occurred after the enforcement of the order; but of late years owing to gradual encroachment within the defined area, malarial fever has been more evident. Greater strictness during the past year with reference to this zone has apparently been beneficial, as shown by the decline of the fever rate from 16·0 to 11·2. This town and a large tract of country neighbouring the Kurnool-Cuddapah canal, which were formerly healthy, were undoubtedly rendered malarious after the introduction of the canal, and the irrigation and leakage which occurred therefrom. A similar instance of the influence of canals upon the health of surrounding areas was investigated by me during the year. Ennur was long a favourite health resort for the people of Madras, before railway facilities to the Nilgiris existed. It was, however, about 1896 attacked with what was popularly held to be a mysterious fever, which, however, at that time was shown by me microscopically to be malarial, and was assigned by me provisionally to physical changes, which I have now been able to confirm. Called away from that work by more urgent duty, I was not able to re-visit the place till 1902, by which time it had been already examined on a more scientific basis, in accordance with present day doctrines, by the Malaria Commission. I found that from Ennur or more properly speaking from Black Town, Madras, up to Muthkur in the Nellore district, there are grades of malaria amongst the population that are at times intense. Without entering into details in this report, I would state that the change in the health condition of this long tract of coast line followed definitely alterations in the structure of the Buckingham Canal, more especially with reference to insertions of locks affecting sub-soil water level, and points of exit of and obstruction to, the surface drainage. Whilst these conditions were being established, changes of configuration of the coast line in certain spots, owing to the action of the Madras Harbour, accentuated results in particular localities. In the case of Ennur, these circumstances were accentuated by extensive embankments due to the railway crossing the back water, and obstructing tidal action. With this was conjoined the possibility of introduction of men bearing malaria, amongst the large number of railway workmen who were assembled. The total result has been an elevation of the sub-soil water in certain areas and the collection of surface water in others, so that the mosquito has been placed under favouring conditions towards multiplication. At any

rate, statistics show that on the east side of the canal where these changes would naturally be most evident, fever has increased out of all proportion to villages on the opposite side. In the portion of the canal extending towards Sadras southwards, no radical changes in structure of the canal took place, nor has there been any increase of fever. So far as the mosquito is concerned, the difference between the two areas found was that, whilst following the course of the canal through Madras to Sadras, the anopheles of Ross (so far as my examination extended solely) was in evidence, the anopheles culifacies and anopheles fuliginosus—the latter more particularly in Tiruvattiyur—were found at intervals. Both these, according to the Malaria Commission, are specifically malaria-bearing compared with the feebly malaria-bearing anopheles of Ross. In this connection, I may state that in the notoriously malarious town of Kurnool during the height of the hot season, I failed to find any anopheles larvæ except a few of the Ross species in pools formed by the waste from public water-supply ; whereas in the village of Dhone in the same district, 30 miles distant from it, in the cold season, I found no lack of anopheles, certain of which do not fit into the character of hitherto described species. Here also the malignant tertian parasite is to be found, whilst along the coast the quartan was in evidence. At Nandyal, I found a single specimen of mosquito that much resembles the anopheles Lutzii, which is said to be an inhabitant of Brazil. It had, however, the distinguishing characteristic of having no ornamental markings on the dorsum of the thorax, and had one very narrow band on its otherwise black palpi.

In Tuticorin, the question arose as to whether certain cases of fever among Europeans was of a malarial or typhoid nature, especially in reference to the supposed evil influence of dredging of the harbour. Malarial fever undoubtedly exists in the town, as well as the anopheles culifacies. The only European however available for examination who had suffered from the fever was the one to whom alone Civil Surgeon Oosman, who had forwarded an able report to me on the subject of the outbreak, was inclined to admit true typhoid symptoms. In this case, I carried out Widal's test and secured a confirmatory reaction. As to the source of infection in this instance, the possibilities were so extensive in connection with highly insanitary milk and water-supplies that it was not feasible to identify the actual cause. The chief fact of importance established was simply that typhoid infection really was contracted in the locality. It was quite evident to me that the European residents ran considerable risks of contracting typhoid not from the foul smelling dredgings of which they complained, but from extensive defœcation by natives which occurred along the front of the beach, in the neighbourhood of their offices. The eating of a cold luncheon in houses where flies and dust could deposit the microbe certainly was the most obvious but unproved factor, having regard to the history of the remaining cases.

In connection with typhoid, Lieutenant-Colonel Sanjana, District Medical and Sanitary Officer of South Canara, has communicated to me statistics which show that typhoid fever was got rid of in the Mangalore Jail subsequent to the introduction of Berkefeld filter plant. Unfortunately, the true significance of the fact is minimized by boiled water having been introduced for drinking purposes during the same period. Yet, the only case of typhoid, which occurred after the period of the introduction of the filter, followed within three weeks of its damage and temporary disuse.

Dysentery and Diarrhœa.—In districts, the total rate per 1,000 of mortality from this cause was 1·0 against 1·1 of the previous year. In municipalities, the rate was 4·5 per 1,000 against 5 of the preceding year. The towns making the heaviest returns under this head were Conjeeveram, Chingleput, Rajahmundry, Madras, Periyakulam, Gudiyattam, Tiruvannamalai, Tinnevelly, Palamcottah, Tuticorin and Vizianagram. It would be an easy matter to say that these towns are notorious for evil water-supplies, and that they have foul soils. But if the case of Conjeeveram be considered, it will be found that it is now supposed to have a sound public water-supply, whereas Chingleput in the same district is not so supplied, and similarly suffers. The truth is, as might be expected from the nature of the disease, that whilst a pure water-supply will aid in prevention, it cannot get over the further difficulty of a badly conserved soil from which must be distributed, by dust and the agency of flies, the causative agents of dysentery and diarrhœa. Persumably, also, certain soils are more conducive to the retention of the causative agent than others. Thus, in the attached nosographical map, it will be found that the chief diseases of the Chingleput district are diarrhœa and dysentery, and its two municipalities form no exemption to liability. Perhaps, in tracing out such matters in detail, it would be possible to show that foul areas with high sub-soil water levels suffer more than those where these conjoined conditions do not exist.

Injuries.—A total of 13,032 deaths from injuries was registered, yielding 0·4 per 1,000 of the population. This represents an advance of 0·1 per 1,000 upon the rate (0·3) which has been returned in seven years of the last decade. This little variability implies that, up-to-date, the population is not largely subject to the various influences of extensive manufactures, mining, shipping and other strenuous endeavours, owing to chief dependence upon agricultural methods. Suicides are included under this head. There was a total of 1,646 against 1,672 of last year. As usual, and in contrast with European countries, suicide of females was in greater proportion to males, namely, 100 to 87·3.

All other causes.—45·7 per cent. of the total causes of death was registered under this head. It can hardly be expected under such conditions of registration that any refinement of sanitary efforts should be possible. It may be argued that, having regard to the difficulty of securing funds for sanitary work in this country, it is possible that there is an already sufficiently large field open to the sanitarian to deal with various diseases classed (albeit somewhat erroneously) under existing heads of registration. But, it is also true that such funds as are available can be used to the best advantage by their being spent for the eradication of diseases definitely located—sanitation is of real utility only when it "touches the spot."

Sanitary Works.

Municipalities.—As stated in my last year's report, a condition of stagnation has overtaken municipal efforts, following the announcement by the Government of India that free grants would no longer be taken in aid of major sanitary engineering works. I am not in a position to judge of the resources of other local bodies in India. But of this I am perfectly certain that the demands on the purse of both municipal and local fund boards in this Presidency are more numerous than in other parts of India, and consequently there is not that elasticity of funds which will permit of the amounts of money required for large sanitary works being obtained in the local market, without some form of monetary aid or guarantee from Government. Tanjore still advertises in vain for a sum of £2,200 to safely dispose of its sewage on a farm that would be highly remunerative! In the meantime, under arrangements formerly existing, Vizagapatam has the benefit this year of receiving its water-supply, and the works for Cocanada are approaching completion. The great City of Madras still depends upon works that distribute, at inefficient pressure, water that has been incompletely protected and is unfiltered, and, with insufficient funds, is attempting to obtain some relief to its sewage soaked soil by its usual expedient of incomplete sewage works. The work of opening up its congested areas remains untouched. Madras is, at this date, a standing illustration of the sanitary inutility and wastefulness of economical and patchwork sanitation. Rajahmundry has at last taken into consideration a scheme I pressed upon it some years back, of opening up an extraordinarily congested and insanitary area in the neighbourhood of Wadi Street. Bellary has proposals of the same character. Negapatam is looking for funds to open up an extremely congested and filthy quarter, and to utilizing the open ground so gained for the erection of a market.

As regards the influence upon fever of the introduction of water-supply when, for reasons stated in my last year's report, statistics are collected for towns where the water-supply is fairly completely distributed, it is found that the total death-rate and the death-rate from fevers have undergone diminution. Thus, in the six towns having an aggregate population of 280,979 for five years prior to the introduction of water-supply, the total death-rate was 30·4, and for the five years ending 1902 after introduction of the water-supplies, it was 26·6 per 1,000; whilst the average death-rate from fever was 8·9 and 4·8 per 1,000 for the same periods, respectively. In contrast with this, in 17 towns without water-supply having an aggregate population of 754,034, the total average death-rate for five years ending 1897 was 27·7; whereas in five years ending 1902, it had increased to 28·1 per 1,000. In the same periods, the average death-rate for fever was 6·5 and 5·8 per 1,000 respectively.

As regards the influence upon cholera of protected public water-supplies in the towns referred to in the preceding paragraph—whilst during the five years previous to introduction of water-supply the death-rate per 1,000 from this cause was 4·1, it was during the five years ending 1902 reduced to 1·8 per 1,000. A further illustration of the influence of water with reference to the spread of cholera is afforded by statistics supplied to me by Lieutenant-Colonel Hakim, District Medical and Sanitary Officer, Trichinopoly. He showed that in that town the incidence of cholera fluctuated according as the public water-works were in a position to give water or not to the town. In 1894, I caused statistics to be prepared that showed very clearly that the Cauvery was a dangerous source of

water-supply, during the prevalence of cholera, from the Coimbatore district down to its outlet. The frequent interruptions in regular working to which the Trichinopoly water-works have been subjected, owing to a series of accidents, seemed to me to afford an opportunity of further elucidating this fact. When in correct order, the works supply the town with water that is derived from an infiltration well placed in the sandy bed of the river Cauvery, and when the connection with this has from time to time got out of order, water direct from the flow of the river was pumped to the town without treatment or filtration. I am by no means a believer in infiltration wells of this nature, as affording anything like the same measure of safety as ordinary slow sand filter beds. Still, that a considerable grade of protection from the cholera microbe is so secured seemed evident from the statistics obtainable. I therefore called for further information. The facts need not here be detailed, but they give clear proof (and it must be remembered the interruptions occurred in various months in several years) that Trichinopoly was very much more free from cholera during those periods when water from the river sub-stream, by medium of the infiltration well, was supplied to the inhabitants than when Cauvery water was obtained from the surface flow direct.

During the year, Government invited the Municipality of Madras to undertake an experiment advised by me to prove that if sewage must find its way into the Cooum, it should do so after filtration, and that under such circumstances it would no longer be a nuisance. Although two consultations were held by me with the Health Officer on the subject and a definite scheme was determined upon, no progress was made on the subject. In the meantime, Government has sanctioned the erection of bacterial filters in connection with the Vaccine Institute, where will be carried out experiments that will determine whether the claim made at Poona that the manurial properties of filtrates of sewage are so infinitely more valuable than crude sewage when applied to land direct, that it will pay to make special works to cause sewage to reach land already completely biologically treated, is really correct. The question is one of considerable importance to agriculture, and is one that will react in favour of the correct disposal of sewage in both urban and rural areas, if there be any solid foundation for the premiss, concerning which I confess myself to be sceptical. Bezwada which had erected some years back rough bacterial filters is still in the position of hoping to obtain a plot of suitable land. Kumbakonam already uses a part of the filtrate of its sewage on cultivated land. The appointment of a Certificated Sanitary Inspector as Secretary to the Salem Municipality has led, amongst other minor sanitary improvements, to the accomplishment of a small scheme, which I had suggested in vain in previous years, for diverting sewage to a bacterial filter, that formerly was received untreated into a river whose connection with cholera spread is notorious. The principle of the bacterial filter is gradually replacing cesspools in towns, in the form of filter-pits, filter-trenches and household sewage filters. Filter trenches used as latrines, when conjoined with hand removal of fœcal matter from the sand surface, have been proved at Periyakulam to afford a cleanly and cheap mode of disposal of urine and ablution water. Sewage farms or sewage gardens continue to be employed with success in Madras, Negapatam, Rajahmundry, Karur, and Guntur. Cropping over night-soil trenches, more especially with the object of inviting attention of ryots to the utility of night-soil is pursued in Erode, Cocanada, Rajahmundry and Palni.

I think steady, though slow, improvement is being made in the important matter of conservancy of towns, by the paying of better attention to the character of the latrines and plant for the removal of night-soil and rubbish. This, amongst other practical results, I consider is largely due to the influence of Certificated Sanitary Inspectors, who now, to the extent of 110, occupy places in municipalities formerly filled by men who had no training whatsoever in sanitation. It is frequently held by those who forget if money is spent at all, it should be spent on recognized principles where sanitation is concerned, that the possession of Certificated Sanitary Inspectors has implied an extension of cost on account of salaries out of proportion to results, and that the old and cheap type of men who were simply drivers of conservancy coolies was sufficient for requirements—the "good enough" policy. As a fact, however, whilst I have urged that municipalities should possess trained men, I have as consistently advised Government to require them to get rid of the numerous petty posts on small pay for which there was a constant predilection. As a result, certain of our larger towns spend less, and the majority but very slightly more, upon their supervising sanitary staff to-day than they did in 1891.

District Boards.—Improvements effected by District Boards are not of a nature that can be demonstrated on paper to have much influence on the course of sanitation. So long as the present organization of local fund bodies exists, whereby petty sums are distributed to

numerous petty bodies, it is not possible that any substantial improvements can be secured. Nevertheless, progress has doubtless been made in minor improvements, such as repairs to wells, improvements to tanks, erection of latrines, slaughter-houses and the like. During the year 34 Certificated Sanitary Inspectors were entertained by the district boards, representing one Certificated Sanitary Inspector for every 4,000 square miles under the administration of these bodies. These new functionaries have been received amongst certain district officials with very much of the conservatism and prejudice with which a new shaped hat or a new fangled rifle, is usually accepted by the British Army. As an illustration of this conservatism, I would state that a report, which reached me during the year, of a fair and festival at which 13,000 people had assembled, bore the recommendation by the reporting officer that a sanitary establishment should be employed in future years, there having been neither arrangements for protection of water-supply nor conservancy, nor as to any other detail in connection with sanitation ; although in former years, under like circumstances, cholera had been epidemic at this festival. The remark of the civil officer responsible was laconic, but to the point. It was contained in the single word—"rubbish." Conceived in the same absence of appreciation of sanitation was the objection of a municipal council, also received during the year, concerning the adoption of a pump or lift, in lieu of allowing the people to withdraw water direct—involving the dipping of chatties, hands and feet—from an important water source ; they held that if machinery were used it would "infuse in the water a strong iron or copper smell"—dirty hands and filthy feet were not to be compared to this risk ! Nevertheless, in the opinion of the older and more experienced of district officials, I think it has been perceived that the existence of a trained sanitary staff is not devoid of utility, when such practical work as dealing with plague and cholera epidemics is forthcoming.

Both district boards and municipalities continue to adopt more or less careful measures in connection with large fairs and festivals. The preventing of the spread of epidemics from such centres has been long regarded as necessary in this Presidency. Indeed, the subject of fairs and festivals, was one of the first treated by the Sanitary Commission in 1863. Certain festivals, such as those at Conjeeveram, Tiruvannamalai and Tirupati were recognised as the starting point of the diffusion of cholera throughout the Presidency. But though, as already exemplified by the remark above quoted, in certain areas lack of supervision is still possible, the general tendency has been to improvement of sanitary arrangements at these important gatherings, with the result of their no longer being dreaded as foci for epidemics. For example, the occurrence of 645 attacks from cholera alone at the festival at Conjeeveram in 1831 which, judging from a record in my possession, seems to have been no extraordinary occurrence, would hardly have been regarded with equanimity in 1902. Cholera seventy years back was no more virulent a disease than it is at this date—the difference is due solely to the advance of sanitation in the interval.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY FOR 1902.

(*Lieutenant-Colonel J. W. Clarkson, I.M.S.*)

General Population.

European and Eurasian Vital Statistics.

The European Census population of 1901 in the Bombay Presidency exclusive of Cantonments in quasi-foreign territory, is 18,804. During the year 1902, 251 births and 302 deaths were recorded against 217 and 251 in 1901. A birth-rate of 13·35 per 1,000 against 11·54 in 1901 and a death-rate of 16·06 against 13·35. By sexes 133 males and 118 females were born against 120 and 97 in 1901, and as regards deaths 189 males and 113 females died against 162 and 89 in 1901.

The Eurasian Census population of 1901 is 6,557. During the year 1902 the births registered were 140 against 133 in 1901 and deaths 154 against 180, the rates being 21·35 per 1,000 against 22·84 in 1901 and 23·49 against 27·54. Of those born, 68 were males and 72 females against 66 and 67 in 1901; as regards deaths, 84 males and 70 females died against 95 and 85 in 1901.

Native Population—Vital Statistics.

Births.—In the Presidency of Bombay, including Sind, during the year 1902, there were 631,393 births registered against 465,647 in 1901. The recorded births for the year under report were thus 165,746 in excess of the number registered in the previous year, and also in excess by 10,384 over the decennial mean ending 1901. In eleven districts only, Khándesh. Násik, Thána, Kolába, Ahmednagar, Poona, Ratnágiri, Bijápur, Panch Maháls, Sukkur and Upper Sind Frontier, did the number of births exceed the deaths. The recorded birth-rate for the year was 34·16 per 1,000 against 25·19 in 1901 and a decennial mean of 33·06. The number of births recorded during the year was higher than in 1901 in all the collectorates except Kánara and the district of Upper Sind Frontier. The general birth-rate rose during the year owing to the diminishing effect of famine. In Kánara, especially in the forest area, the birth-rate continued low owing to malarious causes. In the Upper Sind Frontier the low birth-rate is due to defective registration.

There were 327,549 male and 303,844 female births recorded during the year against 242,382 and 223,265 in 1901. For every 100 female births 107·80 male births were recorded during the year.

The following statement shows the number of births recorded in each year since 1892:—

Year.	Number of Births.	Year.	Number of Births.	Year.	Number of Births.
1892	650,667	1896	691,847	1900	505,662
1893	664,305	1897	629,693	1901	465,647
1894	660,268	1898	582,371	1902	631,393
1895	674,304	1899	685,348		

The greatest number (58,310) was registered in the month of October and the least (43,115) in February. The highest and lowest registrations in 1901 occurred in the months of October and March. Whilst for the decennial 1892-1901 the maximum number of births also occurred in October and the lowest number in February. The rise in the birth-rate from the low rates obtained in the famine years of 1900 and 1901 was marked.

The recorded birth-rates among the urban and rural populations of the Presidency were 27·09 and 35·23 against 22·72 and 25·57 in 1901. Except in the collectorates of Dhárwár, Kánara, Kaira, and throughout Sind, the birth-rates were higher among the rural than the urban population. The difference is very marked in the Poona and Násik collectorates where the rural birth-rates are 40·93 and 45·18 against 14·83 and 22·80 among the urban. The chief cause of the difference in the urban and rural birth-rates is due to defective registration. Plague was a contributory cause. Correct results can never be obtained without compulsory registration. In Sind registration is apparently very defective. In the Upper Sind Frontier District the birth-rates among the rural and urban population were nearly the same, viz., 21·41 and 21·44 respectively.

Out of 56 towns and 7 cantonments in the Presidency, 7 had a birth-rate exceeding 40 per 1,000. Poona, Alibág, Karád, and Kalyán Towns and Ahmedabad, Deoláli, Kirkee, and Ahmednagar cantonments have very low birth-rates. It is notorious many towns do not register their births correctly and until Municipal By-laws are strictly enforced efficiency will not be obtained.

Deaths.—Among the Native population in the rural, town and cantonment circles in the Presidency 721,462 deaths were registered during the year 1902. In 1901, 686,134 deaths or 35,328 less than in 1902 were recorded. Of the total deaths registered, 369,491 occurred among males and 351,971 among females against 357,586 and 328,548 respectively in 1901.

The following statement shows the number of deaths recorded in each year since 1892 :—

Year.	Number of Deaths.	Year.	Number of Deaths.	Year.	Number of Deaths.
1892	611,742	1896	596,472	1900	1,318,783
1893	511,831	1897	749,916	1901	686,134
1894	607,179	1898	548,825	1902	721,462
1895	538,540	1899	672,269		

The death-rate per 1,000 in 1902 was 39·04 against 37·12 in 1901 and a decennial mean of 36·42.

The millesimal rate of males dying to males living was 38·77 and of females dying to females living was 39·32. In 1901 these ratios were respectively 37·52 and 36·70. For every 100 females who died, 104·98 deaths among males were recorded, but these proportions vary considerably as in Bombay City the ratio of males to females death was 134·82, in Karáchi collectorate 122·90 and Násik 108·70.

In the Western, Central, Southern, Gujarát and Sind Registration Districts the number of deaths recorded in 1902 were 188,727, 170,508, 151,785, 133,831, and 76,611 and their ratios per 1,000 42·71, 35·08, 46·07, 49·54 and 23·90 respectively. The highest death-rate occurred in the Gujarát Registration District, fever causing 26·28 of deaths and plague 6·54. The next highest rate took place in the Southern Registration District which suffered to a considerable extent from plague (18·87).

In the year 1902 the recorded death-rates per 1,000 of population, which ranged from 63·13 in the City of Bombay to 17·66 in the Upper Sind Frontier, were higher than in 1901 in all the collectorates except Thána, City of Bombay, Kolába, Ratnágiri, Belgaum, Dhárwár, Bijápur, Kánara, Broach, Ahmedabad and the district of Thar and Párkar.

Comparing the birth and death-rates in each collectorate for 1902, calculated on the census of 1901, the birth-rate in the City of Bombay was much below the registered death-rate 22·85 and 63·13 respectively; this may be ascribed partly to plague. In the

following collectorates the recorded birth-rates are lower than the registered death-rates :— Sholápur, Sátára, Belgaum, Dhárwár, Kánara, Surat, Broach, Kaira, Ahmedabad, Karáchi, Hyderabad, Lárkána, and Thar and Párkar.

As regards deaths by ages, the figures show per 1,000 living that the largest number of deaths took place in the period " under one year " and the next in the age period " 60 and upwards," the lowest ratio being in the period " 5 years and under 10."

The number of male births during the year was 327,549, while the male deaths under one year were 66,115 or 201·85 per 1,000. Among females the numbers were 303,844 and 57,842 respectively, the ratio being 190·36 per 1,000.

The " mortality of infants " as shown by the calculation asked for in Government Resolution, General Department, No. 5192, dated 7th September 1901, is very important, but the data are too inaccurate for correct deductions to be made and are misleading, *e.g.*, Bombay City returns an infant mortality of 565·93 male and 523·93 female infants per 1,000 registered births ; Ahmedabad 317·71 and 314·98 per 1,000 ; the whole Presidency 201·85 and 190·86.

Deaths by causes.—The subjoined table shows the deaths in 1902 arranged according to causes and contrasted with the results for 1901 and with the mean of the preceding five years. The " causes of deaths " will be briefly noticed in the next section :—

Causes of deaths.	Mean for 5 years, 1897–1901.		1901.		1902.	
	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.
Cholera	49,509	2·64	13,600	0·74	3,229	0·17
Small-pox	4,568	0·24	5,340	0·29	2,189	0·12
Plague	78,237	4·17	128,259	6·94	184,752	10·00
Fevers	337,137	17·98	291,951	15·80	270,845	14·66
Dysentery and diarrhœa ...	99,186	5·29	60,198	3·26	58,682	3·17
Respiratory diseases	—	—	—	—	59,379	3·21
Injuries	7,262	0·39	7,092	0·38	7,434	0·40
Other causes	219,286	11·69	179,694	9·72	134,952	7·30
All causes	795,185	42·40	686,134	37·12	721,462	39·04

The greatest number of deaths (85,005) took place in December and the least (34,462) in June. In 1901 the greatest and least numbers occurred in October (73,187) and June (37,335).

The recorded death-rates among the urban and rural population of the Presidency were respectively 60·22 and 35·85 per 1,000 of population against 57·85 and 34·01 in 1901. Among the rural population the death-rate was higher than in the urban population in the collectorates of Dhárwár, Kánara and Broach.

Chief Diseases.

Cholera.—In the year 1902, there were 3,229 deaths recorded as due to cholera compared with 13,600 in 1901. The disease was somewhat severe in the collectorates of Karáchi and Hyderabad, where 1,981 or 4·47 and 1,078 or 1·09 deaths per 1,000 of population took place, respectively. Bombay City gave a few deaths every month, but the total for the year amounted to only 75. The collectorates of Sholápur, Sátára, Ratnágiri, Dhárwár, Bijápur, Panch Maháls and Lárkhána were entirely free ; practically also Násik, Kolába, Ahmednagar, Belgaum, Surat and Upper Sind Frontier, as only 1 death was reported from each of these collectorates. Thána and Broach gave 3 each. Ahmedabad 5, Poona 6, Kaira and Thar and Párkar 10 each, Sukkur 11, Khándesh 15 and Kánara 26.

In December 1901, the only area affected by cholera was the City of Bombay, but in January of the year under report, the collectorates of Belgaum and Kánara were affected in addition and 31 deaths were reported in the month. In the months of February, March and April there were 28, 20 and 22 deaths, respectively reported, but in May the mortality rose to 141 deaths out of which 132 were registered in the collectorate of Karáchi. In the month of June the collectorate of Hyderabad was affected and the mortality increased to 791 deaths in this month and reached its maximun in July, in which month 1,676 deaths were recorded. The number of deaths then suddenly fell to 379 in August and continued falling to the end of the year, there being 121 deaths in September, 13 in October and 2 in November. In the month of December 5 deaths were recorded, 4 in the City of Bombay and one in the collectorate of Ahmednagar.

In the year under report, the greatest number of deaths 2,967 occurred in the rainy season of 122 days against 3,371 during the same period in 1901. Whilst in 1901 the greatest number of deaths 5,319 took place in the cold season of 121 days, during the year under report only 84. 163 deaths were recorded in the hot and dry season of 61 days against 4,682 in the same season last year. In the hot and damp season of 61 days (October and November) 15 deaths were recorded against 228 during the same season of 1901.

The following table shows the total number of deaths from cholera in each of the twenty years ending 1901 :—

Year.	Number of deaths.	Year.	Number of deaths.	Year.	Number of deaths.
1883	37,954	1890	3,259	1897	57,109
1884	13,804	1891	17,850	1898	4,368
1885	37,287	1892	42,900	1899	8,579
1886	167	1893	18,853	1900	163,889
1887	25,711	1894	33,588	1901	13,600
1888	36,500	1895	8,890	1902	3,229
1889	32,431	1896	35,404		

Eighteen collectorates were affected by cholera, but in 16 of these the death-rate per 1,000 was very trivial. Of the remaining two collectorates, Karáchi and Hyderabad, which were entirely free last year, recorded a death-rate of 4·47 and 1·09, respectively. The average death-rate per 1,000 for the whole Presidency was this year 0·17 against 0·74 in 1901.

Out of 56 town circles in the Presidency 8 were affected by cholera during the year against 18 in 1901. The largest number of deaths, 354, or 3·14 per 1,000, was recorded in the town of Karáchi. In Hyderabad 167, or 2·43 deaths per 1,000 of population, took place. The City of Bombay recorded 75 deaths, against 197 during the previous year. Six deaths occurred in the City of Poona, while in the remaining four towns—Ahmednagar, Bulsár (Surat District), Ahmedabad, and Jacobabad—there was only one death recorded in each.

The affected area included 378, or 1·46 per cent., out of 25,846 villages in the Presidency, against 916 in 1901. The highest percentage took place in the collectorate of Karáchi, in which 228, or 36·08 per cent., of villages were affected. In the collectorate of Hyderabad there were 128, or 9·07 per cent., of villages affected, and in the remaining collectorates the number of villages affected were below one per cent.

Small-pox.—There were 2,189 deaths from small-pox (1,132 males and 1,057 females), against 5,340 in 1901, and a decennial mean of 4,106. The mortality, although less than that of 1901, and also of the mean for ten years ending 1901, was higher than that of the years 1898 and 1899. The Gujarát Registration District, except Surat, was free from the disease. The Southern Registration District recorded the highest mortality —979 ; next in order comes Western with 700, Sind with 362, Central with 115, and Surat, in the Gujarát Registration District, with 33. In the year under report 25·58 per

cent. of deaths occurred amongst infants under 1 year of age, whilst 39·30 per cent. took place among children 1 to 10 years, the remaining 35·12 being among persons over 10 years of age.

Fever.—There were 270,845 deaths registered under the heading "Fever" (139,817 males and 131,028 females), against 291,951 in 1901; thus there was a decrease of 21,106 deaths compared with the previous year. The decennial mean is 410,625, which includes the deaths from plague for the past six years. The death-rate was 14·66 per 1,000, as compared with 15·80 for the previous year and a decennial mean of 21·86, and this includes the deaths from plague during the years from 1896 to 1901. Like the year previous, the Gujarát Registration District recorded a high death-rate, but much lower than that of 1901. The mortality for the district was 70,978; next comes Sind with 59,811, Western with 56,684, Central with 51,302, and Southern with 32,070. In the collectorates of Ahmedabad, Broach, Lárkána, Kaira, Panch Maháls and Thar and Párkar high ratios are observed; this result is due apparently to famine causes to a certain extent. The number of deaths during the first six months of the year was lower than in the corresponding months of the previous year. The lowest mortality, 15,109, was reported in June, and it gradually rose, month by month, till November, when the highest mortality, 32,012, was recorded, and declined in December, when 29,166 deaths were recorded.

Plague.—During the year under report 184,752 deaths were recorded from plague—an increase of 56,493 deaths as compared with the previous year.

The number of deaths ascribed to plague in each year since 1896 is as follows:—

Year.	Number of deaths from Plague.	Year.	Number of deaths from Plague.	Year.	Number of deaths from Plague.
1896	2,086	1899	96,596	1901	128,259
1897	46,944	1900	33,196	1902	184,752
1898	86,191				

The mortality from this disease during the year was the highest recorded since its first appearance in 1896. All the collectorates in the Presidency except Upper Sind Frontier were affected.

The collectorates most affected were those of Sátára, Dhárwár, Belgaum, Khándesh, City of Bombay, Násik, and Kaira, with a death-rate of 29·37, 29·38, 27·42, 17·58, 18·13, 11·90, and 11·71 per 1,000 of population respectively. In the other collectorates the death-rate from this cause varied from 8·89 in Poona, 8·36 in Sholápur, 7·87 in Panch Maháls to 1·05 in Ahmedabad, 0·36 in Ratnágiri, and 0·01 in Lárkána and Sukkur. The collectorate of Panch Maháls, in which one death was reported during the previous year, returned 2,055 deaths, followed by Ahmednagar with 1,083, against 20 deaths during 1901. The rates per 1,000 for the various Registration Districts were as follows:—Western 11·59, Central 10·28, Southern 18·87, Gujarát 6·54, and Sind 1·16.

In January there were 16,753 deaths reported, and during March the number rose to 18,089. In April there was a substantial fall, which continued till June, when the minimum (1,539) was reached. In July the mortality again rose, and continued to increase, except a slight fall in November, till December, when the maximum number (30,507) was registered.

There were 2,694 towns and villages, or 10·38 per cent., affected by the epidemic, against 1,582, or 6·10 per cent., during the previous year.

Dysentery and diarrhœa.—Dysentery and diarrhœa caused the deaths of 31,333 males and 27,349 females, or a total of 58,682 persons, against 60,198 in 1901 and a decennial mean of 67,036, a decrease of 1,516 against last year, and 8,354 less than the decennial mean.

The deaths ascribed to "dysentery and diarrhœa" during the six years preceding 1897 showed only slight variations, but have, since 1897, shown a great increase. In the famine year of 1897 there was a sudden increase, which is but natural in a year of scarcity,

and was repeated to an even greater extent in the year 1900 ; but in the following year there was a decrease, and in the year under report these deaths fell below the deaths recorded in the previous year and also the decennial mean.

The Western Registration District records the ratio of 5·15 per 1,000 of population, against 4·50 in 1901 and 4·93 the decennial mean. The Central Registration District comes next with a ratio of 4·68, the Southern Registration District 2·57, the Gujarát Registration District 1·44, and the Sind Registration District 0·26. In the Presidency the rate was 3·17, against 3·26 in the previous year and a decennial mean of 3·56. All the collectorates, excepting Khándesh and Sholapur, show lower ratios ; the highest ratio (8·12) was recorded in the collectorate of Khándesh, followed by Sholápur, Násik, Poona, Ahmednagar, Bombay, and Belgaum. The recorded death-rates were 6·37, 5·99, 5·91, 5·45, 4·74, and 3·98 respectively, while in Sátára, Ratnágiri, Bijápur, and Kolába they were between 2 and 4 per 1,000 of population.

In each of the months from January to July the deaths ascribed to these causes were lower than those of the previous year, and were also lower than the decennial mean in the months from February to September, the month of May excepted ; but in the months of October, November, and December the deaths were higher than those of the previous year and also of the decennial mean.

Injuries.—During 1902, 4,107 males and 3,327 females, or a total of 7,434 persons, met with violent deaths. The mortality from these causes is higher by 342 than that reported in 1901, and also higher than the decennial mean of 6,629. Of the 7,434 deaths, 3,242 occurred from drowning, 1,288 from snake bites, 858 from wounding, 214 from hanging, 152 from attacks by wild beasts, 128 from poisoning, and 1,552 from other causes.

Other causes.—The recorded deaths from causes other than those specified number 134,952, or 18·71 per cent. of the total deaths, of which 67,052 occurred among males and 67,900 among females. The number of deaths under report do not include the deaths (59,379) from respiratory diseases as was the case last year.

The highest number of deaths (17,548) was recorded in the city of Bombay, followed by Dhárwár and Belgaum with 14,670 and 12,524 respectively, and the lowest (158 and 136) in each of the districts of Thar and Párkar and the Upper Sind Frontier.

Under this heading all deaths are included which cannot be classed under cholera, small-pox, fever, dysentery and diarrhœa, injuries, and respiratory diseases. The information obtained under this heading is of little scientific value, as the causes of death are not differentiated by the local Registrars.

Respiratory diseases.—The deaths recorded from respiratory diseases number 59,379, of which 30,743 occurred among males and 28,636 among females. The highest number of deaths (7,745) was recorded in the Kaira District, followed by Surat and Khándesh with 6,403 and 4,416 respectively, and the lowest (21, 5, and 3) in each of the districts of Lárkána, Upper Sind Frontier, and the Thar and Párker.

Sanitary Works.

During the year ending 31st March, 1902, there were 165 Municipalities in the mofussil, with a population, according to the census of 1901, of 2,349,729 souls. The total income of these Municipalities amounted to £414,910. Out of this sum £94,760 was expended on improving water-supply, drainage, and conservancy within municipal limits.

There are 23 District Local Boards, with 207 Táluka Local Boards. The entire income of these Boards during the year ending 31st March, 1902, amounted to £295,920, and out of this sum £10,740 was expended on water-supply and drainage.

The Bombay Village Sanitation Act of 1889 has been introduced into 294 villages, there being an increase of only two in the number this year. It would appear that owing to famine and plague, which claim the attention of the district officers, no progress has been made.

The number of selected villages in which the Village Sanitary Inspection Book has been introduced stands at 3,321 ; of this in about 1,518 villages the book has been written up by the officers of the Sanitary Department.

General Remarks.

The famine in Gujarát and the Deccan continued, and at one period of the year there was great apprehension that not only would the food scarcity continue but that in Gujarát a water famine would ensue. The rains which had held off till late in August then came down just in time, and timely falls in November and December were so beneficial that at the close of the year famine relief operations were practically closed.

During the year 1902 there were 24,185 in and 87,025 out-patients treated in 92 famine relief camp and poor-house hospitals and 2,341 deaths. The maximum number of admissions (4,702) was in the month of August. The maximum number of deaths (329) in the month of March. The minimum number of admissions and deaths was of course in December, when only three poor-house hospitals were open.

The greatest number of deaths (1,860) occurred in Ahmedabad District, out of which 669 occurred in the Dhuliakote poor-house, which contained all through a large number of very feeble and emaciated inmates. 216 deaths occurred in the Panch Maháls, 112 in Bijápur, 61 in Kaira, 60 in Sholápur, 28 in Ahmednagar, and 4 in Belgaum.

The chief mortality was due to dysentery and diarrhœa (1,049) ; 57 deaths were due to emaciation—of these 14 occurred in the Dhuliakote poor-house ; 403 were due to fever ; only 2 deaths were due to plague ; and 830 to other causes. There were no deaths either from cholera or small-pox.

There were in all 21 deaths due to starvation ; of these 11 were reported from the Dhuliakote poor-house, 1 from Wáda Taláo relief camp in the Panch Maháls, and one from Sidatpur relief camp in the collectorate of Ahmedabad ; 3 occurred in the town of Godhra, 2 in the city of Ahmedabad, 1 in Broach town, and 1 each in the collectorates of Surat and Dhárwár.

Real sanitary progress has been at a standstill for some years past. One of the chief obstacles to progress, though by no means the only one, is stated to be the want of funds. Sanitary schemes for water-supply are drawn up with much care and trouble only in the end to be shelved, because the financial part is uncertain, as witness the schemes for Dhárwár and Belgaum. If Government desire progress in this direction, aid must be afforded not only by way of loan, but by giving a direct money contribution of part of the cost. It is a matter of regret that out of the 5½ lákhs specially granted by the Government of India in the year 1902, some part could not have been devoted to helping Municipalities in large sanitary works, and I trust the Government of India will be pleased to allow this in future grants.

Municipalities consider themselves so badly off that it is with difficulty they will entertain project for even a water-supply, and although it is a quite sound sanitary proposition that water-supply and sewerage should go hand in hand, if this happy combination is waited for no progress will be made at all. In large towns nearly all sanitary progress depends upon adequate water-supply, and this should be supplied wherever possible, even at the risk of an increase of fever, but no house connections till sewerage is provided for. As regards sewerage, my experience, though many say that it is not suitable for Indian towns, is that nothing but sewers on the latest English methods will adequately remove the night-soil, urine and dirty water from a large Indian town, to outside where, however it may be disposed of, it will cause less harm than if left (as a large part of it is sure to be when removal is done by hand labour) to be absorbed within the inhabited area.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF THE PORT OF BOMBAY FOR THE YEAR ENDING 31ST DECEMBER, 1902.

Summary.—The following table shows that 15,432 vessels of all sorts with 701,964 crew and passengers were examined during the year ended 31st December, 1902, against 34,637 vessels with 886,310 crew and passengers who were inspected during the year preceding. The reduction in the numbers during the year under report was on account of the exemption from medical inspection of a large number of native sailing craft, Shepherd's Ferry steamers and other vessels which plied between the Port of Bombay and the ports on the mainland, bounded on the north by the Thána Creek and on the south by Nagothna and Roha, as per Government Notifications No. 1697-P. of 17th April, 1901, and No. 3,963-P. of 30th September, 1901.

The clothing and bedding of 93,479 crew and passengers of outgoing and incoming vessels were disinfected. Of this number 79,338 were native crew and third class or deck passengers who left the Port of Bombay for ports out of India; 8,359 were crew, prisoners-of-war, and British troops who arrived by transports from Durban; 1,260 were passengers from East African ports among whom cases of jigger were detected; 3,570 were pilgrims who returned from Mecca via Aden and other routes; and 952 were passengers who arrived by other infected vessels. The table further shows that 40 vessels on which cases of infectious diseases occurred were disinfected, and that 252 persons among whom cases of small-pox occurred were vaccinated. It also shows that at the outward and inward inspections and on board vessels lying in the harbour and docks, 44 cases of plague, 2 cases of cholera, 11 cases of small-pox, 106 cases of measles, 67 cases of chicken-pox, 30 cases of jigger, 3 cases of enteric fever and 1 case of scarlatina were detected. Chicken-pox is not one of the diseases declared by the Government of India as infectious under the Indian Ports Act, but commanders of vessels do not, as a rule, undertake the risk of conveying persons suffering from it to other ports where it may be considered as an infectious disease.

Statement showing the summary of the Shipping of the Bombay Port and the work in connection therewith for the year ending 31st December, 1902 :—

Vessels, including Country Craft.	Total Number of Vessels.	Number of Vessels inspected.	Number of Persons inspected, including crew on vessels.	Number of Native Crew and 3rd Class or deck passengers disinfected during the year.	Number of Vessels disinfected.	Number of Persons vaccinated.	Number of Persons segregated or rejected.*	Diseases and Number of Cases of each.								
								Plague.	Cholera.	Small-pox.	Measles.	Chicken-pox.	Jigger.	Leprosy.	Enteric Fever.	Scarlatina.

* These figures are supplied by the Customs Department and the Port Officer, Bombay.

Incoming Vessels.—In accordance with the rules in force medical inspection and disinfection were imposed on vessels which were actually infected, or suspected to be infected, with plague, cholera, small-pox, measles, scarlatina, black leprosy or other infectious disease on or before arrival at Bombay. Inspection for jigger was compulsory in the case of all vessels from East African ports. 98 vessels of various kinds with crews

of 8,154 persons and 17,119 passengers were inspected on arrival here. Six of these vessels were hired transports which arrived from Durban with 8,359 Boer prisoners and military details. Among the prisoners, 94 cases of measles and 3 cases of enteric fever were detected. The disinfection of the transports and of the clothing and bedding belonging to the crews, prisoners and troops was carried out under the supervision of the Port Health Officer. 59 vessels arrived from jigger-infested ports. They landed 118 cases at intermediate ports, and on arrival here had 30 cases of ulcers due to jigger and 1 case of small-pox. The patients were removed to the Goculdas Tejpal Hospital for treatment. These jigger-infested vessels as well as the clothing and bedding of their passengers, who numbered 1,260 in all, were disinfected. 21 vessels with 3,570 pilgrims arrived from Jeddah and had one case of small-pox. The clothing and bedding of the pilgrims were disinfected before they were made over to the Protector of Pilgrims for disposal. The remaining 5 vessels had on board 1 case of plague, 2 cases of small-pox, 7 cases of measles, and 5 cases of chicken-pox. The vessels and the kit of the persons among whom the cases occurred were disinfected.

His Majesty's ship "Pomone" arrived here with several cases of beri-beri, of whom 12 of the worst were sent to St. George's Hospital. At the request of the Naval Authorities the Port Health Disinfection Barge was placed at their disposal for the disinfection of the linen and clothing and bedding belonging to the vessel and to all on board. The Health Officer has no power to deal with cases of beri-beri, as it is not one of the diseases declared by the Government of India to be infectious under the Indian Ports Act.

The orders regarding the medical inspection of vessels arriving with horses from Australia have been cancelled, *vide* Government Resolution No. 6632 of 30th September, 1902. Consequently no such ships were visited by the Port Health Staff after that date.

In accordance with Government Resolution No. 2969 of 28th May 1902 vessels arriving from East African Ports were inspected with a view to detect cases of sleeping sickness. Up to the present no case of that disease has been discovered here.

Outgoing Vessels.—In accordance with the Medical Inspection Rules, published under Government Notification No. 3892-P., dated the 14th June, 1899, and Rule I. issued under Government Notification No. 2671-P. of 30th September, 1902, the medical examination of the crew and passengers of all vessels and the disinfection of the clothing and bedding of the Asiatic and African members of the crew, who were not officers, engineers, doctors, or Japanese, and of the deck third and fourth class passengers, and Asiatic and African servants bound for ports out of India were carried out immediately before they left the port of Bombay. The inspection of the crew and passengers was done by day, on shore, in sheds specially arranged for that purpose. The disinfection was carried out at the Disinfection Shed which is situated on the Frere Road, near the Prince's Dock.

During the year under report, 15,313 outward bound vessels with 239,040 crew and 437,651 passengers were inspected. At the inspection 3,289 persons were rejected. Twenty-eight cases of plague, 7 cases of small-pox, 1 case of measles, and 51 cases of chicken-pox were detected at the time of inspection.

Of the 15,313 outgoing vessels, 345 vessels with a crew of 34,067 persons and 32,177 passengers left far Aden or ports in the Red Sea and Europe ; 608 vessels with 38,596 crew and 42,607 passengers for other ports out of India, and the remaining 14,360 vessels with 166,377 crew and 362,867 passengers for Indian ports including Burma.

The clothing, bedding, boxes, and other suspected articles of 42,133 Asiatic and African members of the crew, and of 32,277 third and fourth class and deck passengers who sailed on steamers bound for ports out of India were disinfected at the place mentioned in paragraph 7 of this report. In addition to this disinfection, the kits of 4,155 crew and 773 passengers who sailed in native craft were also disinfected. Thus the total number of outward bound crew and passengers whose clothing, bedding, &c., were disinfected comes to 79,338 during the year under report, against 70,914 during the year preceding.

The Disinfection Shed was fitted with another Equifex sterilizer so as to enable the staff to get through the disinfection of the kit of crew and passengers of several vessels sailing about the same hour. The fitting up of the extra stove saved some vessels some delay and inconvenience.

As the disinfection of clothing and bedding by sulphur fumes is not recognised by the Venice Sanitary Convention, and as it is not in accordance with the orders laid down in the Appendix to the Medical Inspection Rules framed under the Epidemic Diseases

Act, arrangements were made with the Military Authorities for carrying out the disinfection of the clothing and bedding of all Native details by the Port Health Department.

The crew and passengers of four steamships which called at this port merely to land or embark passengers, were exempt from inspection and disinfection of their clothing and bedding in accordance with the proviso to Rule I. of the Medical Inspection Regulations. Such of the crew and passengers as embarked at Bombay on the vessels were inspected, by day, on shore; the new Native crew and the third and fourth class and deck passengers had their effects disinfected.

Infectious Diseases on Vessels in the Harbour.—Between 1st January and 30th June, 1902, 10 steamers and 11 Native sailing craft, which were lying in the docks and at the different bandars in the harbour, had on board 10 cases of plague, of whom 8 died; 2 cases of cholera, both of which proved fatal; 4 cases of measles; 5 cases of chicken-pox; and 1 case of scarlatina. In addition to these cases, 5 labourers were found dead in the Prince's and Victoria Docks and at Modi Bandar (Shepherd's Wharf). The deaths were reported to have occurred from plague. The disinfection of all these vessels and those referred to above under incoming vessels, as well as of the places where the dead bodies were found, was thoroughly carried out in accordance with the regulations. There was no case of plague or other infectious disease on vessels which were at anchor in the harbour during the period extending from 1st July to 31st December, 1902.

TABLE GIVING DETAILS OF INFECTIOUS DISEASES ON VESSELS WHILE LYING IN THE PORT OF BOMBAY DURING THE YEAR 1902 :—

Months.	Number of Persons who were attacked with Plague at Bandars and in the Docks.		Total Number of infected Vessels.	Total Number of Cases of Infectious Diseases in the Bombay Harbour.

Total for 1901			38	5	5	4	—	3	—	12	—	19	14	—	—		

Port Observation Camp.—The present area of land occupied by this Camp is 12,555 square feet, the monthly rent for which amounts to Rs. 87-14-2. Among the passengers and crew who were sent to the Camp 28 developed plague, and were transferred to the various hospitals in the city for treatment. The sheds of the Camp in which the plague cases developed were thoroughly disinfected with perchloride of mercury and were kept unoccupied for some days. The thorough disinfection of all the sheds was carried out frequently with the standard solution of perchloride of mercury. One hospital assistant

and one ayah were employed to look after the patients in the Camp. One of the Medical Officers was detailed in turn every month to supervise the general working of the Camp.

Disinfection of Ships and Infected Cargo.—During the year 61 vessels of all sorts were disinfected under the personal supervision of the Health Officer of the Port or of his staff. In certain instances the disinfection barge was placed at the disposal of the Naval and Royal Indian Marine authorities to carry out the disinfection of linen, mattresses, clothing and bedding belonging to Naval ships and transports.

A man was reported to have been found dead of plague on some bags of cotton seeds at the North Jetty extension, Prince's Dock. Twenty-five of the bags of seeds which were supposed to have been in contact with the deceased were disinfected by saturated steam under pressure. The cotton seeds were not destroyed by the process of disinfection, 20 bags of bones on board a country craft infected by a case of plague were also disinfected.

The vessels on which cases of cholera occurred had the drinking water which was stored on board discharged into the sea. The water-tanks were thoroughly disinfected inside with potassium permanganate solution before they were refilled with a fresh supply of drinking water.

General Health of the Shipping.—During the year, 996 persons connected with the shipping were admitted into the various hospitals in the City. The Saint George's Hospital admitted 558 European patients, of whom 20 died, 495 were discharged, and 43 remained after 1st January 1903 under treatment. The Jamsetjee Jeejeebhoy Hospital admitted 171 Native patients, of whom 11 died, and the Goculdas Tejpal Hospital 267 Natives, of whom 18 died. The diseases for which the patients were admitted were small-pox, measles, continued enteric and remittent fevers, dysentery, beri-beri, syphilis, gonorrhœa, debility, rheumatism, bronchitis, diarrhœa, pneumonia, abscess, ulcers, etc.

Red Sea Pilgrim Traffic.—Bombay was opened as a port of departure for pilgrims in accordance with Government Notification, General Department, No. 6051, dated the 5th November 1902. On receipt of this Notification steps were at once taken to clear the ground at Pir Pao and erect camps there. The Public Works Department had the first camp for 300 open on the 1st December, 1902, and 285 pilgrims were taken into it on that date for segregation for 10 days and after their clothing and bedding had been disinfected at the disinfection Shed on the Frere Road, near the Prince's Dock. Subsequently more pilgrims were found waiting in Bombay and advantage was taken of the offer of one of Mr. Essaji Tajbhoy's hulks free of rent. 341 pilgrims were segregated on this hulk for 10 days from the 3rd December. The second camp at Pir Pao for 420 pilgrims was ready on the 10th December, but pilgrims for it were not brought before 17th December, on which date 333 souls were admitted into it. As more pilgrims offered, and as the time for segregation was very short, some 22 tents (each of which was capable of accommodating 20 fighting men or 25 followers on service) were at once borrowed from the Arsenal, and 262 pilgrims were admitted into some of these tents on 22nd December.

The sanitary arrangements were attended to by a staff of male and female sweepers, and the excreta was removed and emptied into the sea. None was allowed to soak into the ground as the camps may be used next year and there was also the risk of contaminating the drinking water in the wells. The camps and grounds were constantly swept during occupation, and the huts were limewashed by the Public Works Department after being vacated by each batch of pilgrims.

In addition to the above 1,221 pilgrims who were segregated for 10 days in Bombay, 83 pilgrims from the provincial camp at Peshawar were received on 15 December which made a grand total of 1,304 pilgrims who passed through the camps from 1st to 31st December 1902.

The following pilgrim ships left Bombay on the dates shown :—

S.S. *Shahanoor*	left with	709	pilgrims	on 15th December,	1902.
„ *Ahmadi*	„	577	„	31st „	
		1,286			

During segregation 2 pilgrims died of debility and old age.

The pilgrim ships which left Bombay for Jeddah had no cases of plague or any other infectious disease during the voyage.

Inland Pilgrim Traffic.—Twenty-one vessels brought to Bombay 3,570 pilgrims from Mecca via Aden and other routes. The baggage of these returning pilgrims was

disinfected in the Port Health Disinfection Stoves. Pilgrims whose homes were up-country or beyond the frontier were not allowed to enter the town, but were handed over to the Protector of Pilgrims so that they may be sent direct from the Disinfection Shed to their homes by rail.

Sanitary State of the Harbour and Foreshore.—The sanitary state of the foreshore and of the various bandars, basins and docks has been reported as fairly satisfactory.

Cholera, Small-pox and Plague in the City.—The public mortuary returns show that 75 deaths from cholera, 288 deaths from small-pox and 13,820 deaths from plague occurred in the City.

Each individual who left this port was subject to a rigorous and searching examination for the detection of any symptoms suspicious of plague. In addition to this examination the personal clothing and bedding of such crew and passengers as came under the disinfection rules were thoroughly disinfected. This strict examination and disinfection have become so well known that very few persons actually suffering from plague attempt to travel by sea, as they know they will not be allowed to sail and may be detained in the camp or hospital.

Due intimation of any cases of plague which were known to have developed among the crew and passengers who were prevented from sailing to ports out of India was sent to the Government in order that the information may be communicated by wire to the authorities at the next port for which the vessel was bound. When a plague case occurred among those who were rejected from vessels bound for Indian Ports the fact was made known by the Port Health Officer to the authorities at the next port where the vessel was to call. This procedure was adopted so that other ports may have full information of what had taken place and be in a position to protect themselves.

Forty-four cases of plague were detected at the outward and inward inspections and in vessels lying in the docks and harbour. This decrease in the number of cases detected is due to the fact that a great number of the rejected were turned into the town and were lost sight of, whereas in the years in which a large number of cases were detected, the persons who were rejected at the inspections were detained in the various camps which existed at the time until they showed clear signs of plague or until it was certain that the symptoms from which they suffered were not due to plague.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1902-1903.

(*R. T. Greer, Esq., Chairman.*)

Suburban Drainage Works.—It is gratifying to note that the whole of the works comprising the Suburban Sewerage Scheme have received the sanction, both of the Corporation and of the Government of Bengal. They are being carried out under eleven separate contracts, eight of which have been executed, the works to which they relate being in progress. At the close of the year tenders were being invited for the remaining three contracts. The Engineer's report of the 31st December, 1901, which dealt with the sewerage of Alipore and Kidderpore Districts, with the addition of Main Sewer No. 1, and its branches, were adopted by the Corporation in April, 1902, and received the sanction of the Government in May, 1902. His report of the 1st July, 1902, which embraced the remainder of the scheme (the construction of sewers in the amalgamated area between Palmer's Bridge and Tolly's Nullah, in Wards 19, 20, 21 and 22) received the sanction of the Government in November, 1902. These latter works were remodelled and redesigned on the recommendation of Mr. Baldwin Latham and of a Committee of Engineers who scrutinised the proposals. The whole of the sewerage works are estimated to cost £446,000. It is expected that considerable progress will be effected during the coming year.

The Corporation have also approved the Engineer's Scheme for the drainage of Belliaghata, the estimated cost being £8,185. The measure, however, has not yet received the sanction of Government. A scheme for the drainage of the Fringe Area should be ready before the close of the current year. A surface drainage Scheme in connection with the Suburban drainage is under preparation.

The Water-supply.—The total quantity of filtered water supplied from the main works at Pulta during the year was 7,542,012,530 gallons, a slight increase upon the previous year, the average consumption per head of the population being reported as 24·23 gallons. During the year 2,304 feet of pipes were added to the system, bringing the total mileage of filtered water mains and services to 317·34 miles, of which 184 miles are within the town area.

Some progress has been made in carrying out the scheme for the conversion of the present intermittent supply into a continuous system, which was approved by the Corporation in May, 1902. The area reported to have been brought under constant supply and control of waste-water meters includes the western portion of Ward No. 1, the whole of Ward No. 2 and part of Ward No. 3, in the Tallah Pumping Station sphere, and parts of Wards 6 and 8 in the area served by the Halliday Street Pumping Station. The work done includes the fixing of 37 Deacon's waste-water meters and 5,356 stopcocks for house-connections, and the substitution of unfiltered for filtered water in 1,089 privies throughout the town. The wastage in the area under the control of waste-water meters has been greatly reduced, but it is still enormous in the remainder of the town. Special monthly reports are submitted on the progress of the work under the scheme, and are considered by a special Sub-Committee. It has been felt that better progress might be made by increasing the staff, and the Commissioners have accordingly sanctioned the appointment of an expert for three years on a salary of £50 per mensem. This officer will work independently of the present Assistant Engineer, and will be given charge of a separate area with an appropriate staff.

The new additional reservoir at Tallah is being constructed, and will be ready for use in a few months' time.

The total quantity of unfiltered water pumped through the mains during the year was 5,659,865,427 gallons, the average consumption per head of the population being

shown as 19·24 gallons. No less than 74,408 feet or 14·09 miles of unfiltered mains were laid down during the year, bringing the total mileage to 172·24 miles, of which 134·72 are in the town area. The expenditure on the extension of the unfiltered supply amounts to over £27,600, the pipes alone costing £20,230.

Bustees.—The work of the Bustee Department has been carried on mainly on the same lines as in the previous year. The work of the Special Plague Department in demolishing plague-infected huts operated towards the improvement or clearance of bustees. In many cases the owners, seeing the removal of obnoxious huts, used the opportunity to utilise the land for pucca dwelling-houses and thus brought about a permanent improvement in the locality. Two hundred and twenty-eight huts have been demolished during the year thereby removing some of the most insanitary plague spots in the city. The General Committee have finally approved the standard plans in the case of thirthy-one bustees whose insanitary condition had been specially reported. The Corporation have determined to acquire Goomghur Bustee and to open out Manick Bose's Ghât Bustee by making several new roads. It has been found that owners who have valuable lands in the town, when called on to make improvements in their bustees, prefer to build masonry structures on their lands. Two bustees, for whose improvement plans had been prepared, have been entirely cleared away, and three others have been partially demolished during the year. In several other cases the owners are erecting pucca buildings.

To prevent the repetition in the added area of the insanitary conditions existing in the bustees in the town, a special temporary staff of Surveyors has been employed to make alignments, as provided for in the Building Sections of the Act, for growing bustee areas in the suburbs. The system is still in an experimental stage, and any report as to its effectiveness would be premature although there is promise of good results. The standard plans provide for suitable roads and passages, lane and court-yard space, surface drains, and latrine and bathing accommodation. There appears to be no special cause for the condemnation of the bustee system of hut dwellings on sanitary grounds, provided that sufficient care is taken in these particulars and measures are enforced against overcrowding.

In any scheme for a general improvement of the health of the city the remodelling of bustees must occupy a foremost place. Overcrowding, want of air space, light and drains, and the absence of proper sanitary conveniences are the prominent faults in existing bustees, and these can be remedied only by wholesale measures. The provision of accommodation for the surplus population must accompany any properly devised scheme for the demolition of insanitary bustees. Public opinion appears to be unfavourable to the construction of blocks of model dwellings for the labouring classes out of the funds of the Corporation, and in view of many failures in this direction in European cities, the success of any experiment of the kind in Calcutta cannot be considered as a certainty. The Corporation are taking steps to provide such dwellings for their menial staff, and will thus afford a good object lesson to landed proprietors. The suburbs offer suitable opportunities for those whose occupations do not require them to reside in the interior of the city, and they form the bulk of the labouring classes. The creation of wide thoroughfares in the suburbs with municipal conveniences and cheap tram-cars, would encourage the movement of the immigrant population to these quarters, and tend to solve the difficulties arising from overcrowding in the interior. The Corporation are pursuing this policy in the south of the city, and at present have in hand schemes more or less advanced for the construction of 60 feet wide roads at a cost of about £140,000. The prospect of the so-called Calcutta Improvement Scheme has checked operations of this kind in the north of the city, but there is land available to the north of Tallah, where the city can readily extend, and the surplus population find ample space for settling down without seriously interfering with their present work. Remodelled bustees will meet the requirements of the remainder and possibly blocks of model dwellings will in time become more popular.

In dealing with the improvement of bustees the operations of the Corporation are now confined to requiring that the necessary roadways and drains are constructed, the prescribed space between huts opened out, and that the necessary Municipal conveniences are provided. An effort is being made to check the growth of insanitary bustees, where huts have been demolished, by prescribing alignments for roadways, and thus providing that new structures shall be free from many existing objections. On sanitary grounds the complete demolition of a bustee is often desirable, the huts being incapable of improvement. The Plague Department have thus satisfactorily dealt with a number of insanitary dwellings. An efficient scheme for the improvement of Calcutta must include provision for the surplus population who are disturbed by demolitions.

Plague.—The mortality from plague during 1902-3 was 8,955, the largest yet recorded in Calcutta since the plague first appeared in the city five years ago. This is due mainly to the severity of the present outbreak, which reached its maximum in the middle of March, when 894 deaths were reported for the week. On the other hand, the figures for the quiescent (inter-epidemic) period, namely, from July, 1902, to January, 1903, are the lowest recorded for the past three years. The onset of the present epidemic took place later than usual, but the mortality from plague increased with such rapidity that, by the end of January, all the former totals for that period of the year had been left behind.

There appears to be no doubt but that the type of plague has been more virulent during the present epidemic than in any of the previous ones, the high case mortality being the subject of remark amongst both patients and practitioners. The progress of the epidemic could be traced from the usual plague-centres in the city, namely, the dâl and grain godowns in Jorabagan, Ward V, and in Chitpore-Ahiritolla Bustees, Ward II, to the grain godowns in their neighbourhood, and later to the wards in the south-eastern districts of the city and to the added areas. As in previous years there has been a widespread epidemic amongst rats, which began in Ward II, reached its maximum in the beginning of January, and declined before the epidemic amongst human beings broke out. The fact tends to support the belief that rat mortality precedes the appearance of epidemic plague.

The chief remedial measures have been the disinfection of plague-infected rooms and huts and the demolition of the latter under the Plague Regulations where disinfection could not be efficiently carried out, adequate compensation being paid to the owners. The demolitions have been effected in most cases by the hut-owners themselves.

The attitude of the people has been more friendly than in former years. The poorer classes appear to have gained more confidence in the officers of the Plague Department, and they have rendered greater assistance in reporting plague deaths than heretofore. The amount of voluntary evacuation of plague-infected dwellings in Ward V, especially, has been striking, and disinfections have been frequently applied for.

There were only nine (9) applicants for inoculation with Haffkine's serum.

Health Department.—The Health Officer reports that the death-rate of the town during 1902-03 was 37 per 1,000, due in a large measure to the recurring epidemic of plague in the first half of the year. Excluding this factor, the figure is reduced to 28·4, which is only slightly above the mean of the decade, or 27·4 per 1,000. Cholera accounted for a larger number of deaths than usual, the disease being virulent during the year throughout the province generally. An important reform was introduced in June, 1902, under which all cases of death in the town are inquired into by the Sanitary Inspectors, who, with one exception, are qualified medical men. One result has been the detection of a considerable increase in the mortality from tuberculosis. The Health Officer is of opinion that this disease accounts for fully 10 per cent. of the total mortality, and statistics show that the number of deaths from phthisis and pulmonary disease has more than doubled in the last thirty years.

The birth-rate is low compared with the other Presidency towns, and this may be largely ascribed to defective registration. The Health Officer has recommended the adoption of a system which obtains in Madras, where a number of men on comparatively small pay are employed, each in a circumscribed area, to make local inquiries. The Corporation have decided to give the measure a trial for a year in one of the four Districts.

The work of vaccination has, during the past year, been entrusted to men of the Hospital Assistant class, who have replaced the unqualified men hitherto employed. The Health Officer does not consider that the change, so far, has been for the better, and he describes the vaccination work generally as unsatisfactory. A Special Committee of medical men has been appointed to deal with the subject, and it is proposed to consult the Inspector-General of Civil Hospitals and the Sanitary Commissioner of Bengal.

A new Vaccine Depôt is being constructed at Ballygunge, at a cost of £1,820 exclusive of the value of the land, the acquisition of which cost £590. The Corporation have, during the past year, manufactured their own lymph under considerable difficulties, the Government supply having ceased. It is expected that the new depôt will be ready before next cold weather. New Vaccination Stations and Registration Offices are also about to be constructed in Wellesley Street and Elliot Road.

Under the Reorganisation Scheme, the work of food inspection formed part of the duties of the Sanitary Inspectors. It was found, however, that these Officers could not

devote sufficient attention to their work, and the Corporation accordingly strengthened the Health Department by the appointment of five Food Inspectors, one for each of the four districts and a special officer for Sealdah Station, where large quantities of fish are brought daily by rail. These men occupy the same standing as Sanitary Inspectors. Large quantities of unwholesome food were destroyed during the year, and the Inspectors successfully prosecuted several prominent ghee merchants for selling adulterated articles. An important test case of adulterated mustard-oil was taken before the Magistrate, and the prosecution ended in a conviction. The appeal against the conviction has failed in the High Court.

Conservancy.—The Conservancy of the town is one of the first cares of the Corporation, who do not grudge the payment of any necessary expenditure under this head. The Gowkhana staff has been strengthened, and additional carts and animals have been provided. An improvement is noticeable in the condition of some of the streets, especially where men and boys are constantly engaged in collecting horse-droppings and refuse. Much yet remains to be done, particularly in the matter of providing an efficient afternoon service in the more thickly-populated areas of the native portion of the town where it would be almost impossible, at present, to enforce action under Section 430. When the two new Gowkhanas now under construction in Districts I and IV have been completed, each district will have its own supply and separate staff of animals and carts, and it will be possible to make more efficient provision for the better cleansing of the streets. The improved condition of the Gowkhana animals reflects credit upon those responsible for their care.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1902-1903.

(*Dr. J. Nield Cook.*)

Births.—The birth-rate of the town calculated on the registerd births was 14·2 per 1,000 of the population. In order to ascertain to what extent the low birth-rate was due to defeetive registration, I worked out the birth-rate per 1,000 females between the ages of 15 and 40 in the three Presidency towns, and found that in Calcutta it was 72·1, in Bombay 92·6, and in Madras 175·8. If the Census figures can be relied on and the fecundity of the women is approximately the same in the three towns, it follows that 1·28 births are registered in Bombay and 2·44 in Madras to every 1 registered in Calcutta. It further follows that if the registration in Calcutta were equal to the registration in Madras, the number of births registered would be 22,250, giving a ratio of 26·3 per 1,000 of the population, which is nearly double the rate on the births actually registered. In Madras a number of men on comparatively low pay are employed, each in a circumscribed area, to make inquiries of midwives, policemen, barbers, headmen of hutting grounds, old women and anyone else who is likely to be able to give information of births, and as this system appears to have produced an approximately accurate registration of births I recommend its adoption in Calcutta, and the Commissioners have sanctioned a trial of it for one year in one of the four Districts into which the town is now divided, with a view to its general adoption if it should prove successful. The number of still-births was 4·9 per cent. of the total births including the still-born.

Deaths.—The death-rate of the town was 37. A recurring epidemic of plague in the first half of the year was the cause of this high figure. If this disturbing factor be subtracted from the total deaths the ratio works out to 28·4, which is only slightly above the mean of the decade exclusive of plague, the slight excess being attributable to plague deaths falsely registered under other causes which always happens in an epidemic. Plague was administered by a special department independent of the Health Department, reliance being placed mainly on disinfection. The mortality was rather less than the previous two years, but judging by the course of the disease in the present year, 1903, up to the time of writing, there is no reason to believe that the disease shows signs of weakening. The most remarkable feature is the regularity of its rise and fall, year by year, according to season and locality. Cholera accounted for more deaths than usual. Most of the cases can be traced to the consumption of water from tanks and wells, which are still numerous in the town. It was a bad cholera year in the province generally. In the 24-Perganas which nearly surround Calcutta the cholera mortality was double that of the previous year; consequently many cases were imported and formed *foci* of disease. The deaths registered under "Fevers" were a good deal below the mean, though prevalent in the surrounding districts; the Malarial Commission visited Calcutta and reported that, though the Anopheles Rossii existed in myriads in the native houses, there was no malarial infection of the native children, nor sporozoits in the anopheles. The mortality from small-pox was comparatively low again after two rather bad years, though it was very prevalent in the Province of Bengal, this disease having approximately a five years' cycle in Calcutta. Enteric fever accounted for 81 deaths. This is considerably above the average, but I believe it to be below the actual number, as a number of cases that occur amongst natives are diagnosed as remittent fever. From the month of June all the cases of death that occurred in the town were inquired into and reported on by the Sanitary Inspectors who are nearly all qualified medical men. One result of this was to show a considerable increase in the mortality from tuberculosis, mostly pulmonary phthisis, which, from June to December inclusive, amounted to 6·4 per cent. of the total mortality. I am satisfied that this figure is much too low, and that this disease accounts for at least 10 per cent. of the total mortality of Calcutta. A large number of cases of

The following statement shows the mortality from the principal diseases in 1902 compared with the average of the previous five years.

malarial fever subsequently die of tuberculosis, but are registered under the former head, the pulmonary symptoms attracting but little attention. There is no doubt that a number of cases of abdominal tuberculosis are diagnosed as chronic dysentery, and it is a common practice in the town to call any disease in which dyspnœa is a prominent symptom of asthma, and an impossible number of deaths are registered under this head. The evidence of the hospitals supports my view of the prevalence of this disease, for out of 966 consecutive post-mortems at the Medical College Hospital, in 13·4 per cent. death was due to pulmonary tuberculosis, and in 3·6 per cent. to other forms of tubercular disease. Medical practitioners in the town tell me that the disease is on the increase amongst the well-to-do as well as amongst the poor, and our municipal records show that the mortality from phthisis and from pulmonary disease generally has more than doubled in the last thirty years. Tuberculosis of cattle is a rare disease here, and the Hindus generally do not eat beef. Moreover, it is the general practice amongst natives of this country to sterilise milk and its derivatives, such as ghee, curd, and *channa* before using them for food. This eliminates what is supposed by many to be a common cause of infection, and there is no doubt in my own mind that the disease is spread by direct infection from person to person living together in crowded and ill-ventilated rooms principally by the germ-laden spray of coughing and sneezing being directly inhaled, and to a less extent by dried sputum in dust. The fact that the phthisis mortality has doubled in Calcutta, whilst in England and Germany it has been reduced to about half, points above all to the necessity of adopting a comprehensive policy for the better housing of the poor. But as it will certainly be a long time before any considerable improvement can be effected in Calcutta in this respect, I have recommended the following special measures for dealing with the disease :—

(1.) Careful inquiries by the Sanitary Inspectors or special officers appointed for the purpose, compulsory notification being impracticable.

(2.) Periodical disinfection of affected houses.

(3.) The dissemination of general information by leaflets and in other ways, and instructions how to deal with a case at home and minimise the risks.

(4.) The establishment of a home for advanced cases.

Vaccination.—The total number of vaccinations done during the year was 17,534, which is less than half the number done in the previous year. The falling off occurred in all the four districts, as shown below :—

—	1901.	1902.
District I.	10,074	4,222
District II.	9,669	4,456
District III.	7,026	2,667
District IV.	8,777	6,189
Port	84	—
Total	35,630	17,534

It is evident from the above figures that the causes of the fall were general, affecting all the four Districts. Vaccination was done during the year by hospital assistants, working directly under the District health officers, the inspectors having been abolished. The years 1900 and 1901 were marked by the cyclical prevalence of small-pox, which has now subsided. During the years when the disease is epidemic special efforts are made to get people vaccinated, and they show greater readiness to avail themselves of vaccination. When it subsides there is generally a fall. But making all due allowance for this, I consider that the results are unsatisfactory. I believe that the following causes contributed :—

(*a.*) Both the District health officers and the vaccinators were new to the work.

(*b.*) There were constant changes in the department, the vaccinators throwing up their appointments to take others which were more remunerative or more congenial.

(*c.*) A vaccination department requires more supervision than the District health officers, who have many other duties to perform, can give it.

A new vaccination depôt was built during the year at No. 1, Shikdarpara Street, and the site has been purchased, plans passed, and tenders accepted for the construction of a depôt for animal vaccination and the manufacture of preserved vaccine in Ballygunge. As a temporary measure vaccine is being prepared in the bacteriological laboratory, the calves being kept in a shed in the yard. Some trouble has lately been experienced owing to an outbreak of rinderpest among the vaccinated calves, but that has now been got over and the lymph supply is of good quality. Recently some glycerised lymph has been made as well as lanolised, and it has been found here, as in England, that septic germs decrease rapidly in glycerised lymph, but increase with keeping when it is prepared with lanoline. When the new depôt is opened I propose to give up lanoline altogether in favour of glycerine.

Filtered water supply.—Two samples of filtered water from taps in the town were examined every week, both chemically and bacteriologically, and the results submitted to the General Committee, as required under Section 243 of Act III. (B. C.) of 1899. As in previous years the total solids, chlorine as dissolved chlorides and the total hardness ranged comparatively high from January to June, varying between 20 to 28, 0·7 to 3·7, and 9 to 15·5 parts per 100,000 respectively. The albuminoid ammonia, as determined by Wanklyn's process, and the nitrates varied, within narrow limits, from 0·004 to 0·006 and 0·019 to 0·029 respectively, the "oxygen consumed" ranging from 0·004 to 0·01. No nitrates were present in any of the samples. During the rains there was, as usual, a slight turbidity or opalesence. This can be thrown down by alum in the laboratory ; but as it does not apparently affect the quality of the water but only its appearance, it is not considered necessary to adopt a system of precipitation at the waterworks. About 50 to 60 bacteria to the cubic centimetre were generally found to be present in the town water. The only unsatisfactory feature of the water was the continued presence of bacteria of the Colon group, which were found in every examination of the filtered water in relatively large numbers. Their presence could almost invariably be detected in 0·5 c.c. of filtered water by the formation of gas and acid, and was in some instances detected in 0·2 c.c. In the river water, before settling and filtration, they could generally be detected in 0·1 c.c., and were detected in as small a quantity as 0·01 c.c. There is no evidence that their presence has proved injurious to persons drinking the water, but they cannot but be a cause for anxiety. I attribute their presence mainly to riparian villages, and recommended that measures should be taken for improving the conservancy of the river, but this was regarded as "a counsel of perfection." Bacterial enumerations were made every week from the outlet wells of the 36 filter beds at Pulta, to show whether the filter beds were working efficiently. Any filter that showed over 100 to the c.c. was at once cut off. No definite relation could be shown between the number of bacteria present and the head of water on the beds, or the number of days the filters had been in use. In addition to the above, examinations of 233 samples of water from the river, settling tanks, Tolly's Nullah, and tanks and wells in the town, were made in the course of the year. In 14 samples of tank water comma bacilli were detected.

Other Laboratory Work.—Nineteen specimens of blood were tested for enteric fever, Widal's reaction, and in 12 of them a positive result was obtained. Ten specimens of sputum were examined and tubercle bacilli were found in 3. Fifteen dead rats sent by the Plague Department and one by Messrs. Ewing and Company were examined, and plague bacilli found in 7. In one an organism resembling that of surra was found. I have found it on two or three previous occasions in Calcutta rats. One swab from the throat of a case of suspected diphtheria gave a negative result.

Out of 391 samples of ghee examined and analysed, 139, or 36 per cent., were found to be adulterated ; out of 202 of milk, 118, or 55·9 per cent. ; out of 36 of butter, 2 ; 1 of arrowroot was found to be adulterated ; out of 36 of barley powder, 26 were adulterated ; out of 7 of mustard-oil, 3 were adulterated ; 1 of cornflour was adulterated ; 3 specimens of disinfectants and 20 of a miscellaneous nature were also examined and analysed. The Analyst attended Court on 43 occasions to give evidence in adulteration cases.

A test case for the adulteration of mustard-oil was taken up at the request of the Market Sub-Committee, the Courts having on a former occasion decided that such adulteration was a necessary trade process as it was stated to be by the manufacturers. Evidence was adduced that pure oil was manufactured in the jail, and also by Messrs.

Andrew, Yule and Company, and the case was decided in our favour. Appeals against the Judgment have been made to the Sessions Court and the High Court, but have been dismissed, so it will now be possible to take action to stop this widespread practice in which most of the large manufacturers are concerned.

The question of standards is a difficulty in dairy work in India as it has been elsewhere, and allegations having been made in certain quarters that our standards were unreliable, I was asked for an explanation. Our ghee standards are based on a considerable amount of experiment, but as I quite admit that nothing like finality has been reached as regards standards for India, and the question is an important one considering the enormous quantities of ghee consumed in this country, and the prevalence of adulteration, after discussing the question with some of the leading analysts at home I recommended that a Commission should be appointed by Government, consisting of two experienced English analysts and some good Native chemists to make a tour through the country, make a long series of experiments under the varying conditions of climate and season, and report their results.

Work done by the Sanitary Inspectors.—There were 4,593 notices served for the abatement of nuisance, and 3,195 prosecutions with an aggregate fine of £725. There were 2,289 prosecutions in licence cases, with an aggregate fine of £1,300. The number of cases of disease investigated was 8,501. The number of houses disinfected was 2,972. Bedding and articles of clothing were passed through the Equifex stove and articles of no value were burnt. In addition to this, during the latter part of the year all causes of death other than suspected plague were inquired into and reported on, with a view to getting more accurate returns of the causes of death, which formed a very heavy addition to the work of the Inspectors. The licence cases alluded to above were not so much for neglect to take out licences, as for carrying on trades in insanitary premises for which licences had been refused until the sanitary defects were remedied. As there is no special course of practical training in Bengal for sanitary officers, I have recently made proposals for the establishment of such a course of instruction with examination; for certificates in connection with the Sanitary Institute and a Museum of Hygiene for teaching purposes.

ABSTRACT OF THE REPORT OF THE MADRAS MUNICIPALITY FOR 1902-03.

(*S. D. Pears, Esq., President.*)

New Drainage Works.—The laying down of the Cast Iron Main was in progress, 10,931 lineal feet were laid. The main may now be said to be nearly complete with the exception of a gap in Napier Park about 166 feet long, and another near the Mylapore Pumping Station—about 460 feet long. The construction of the engine and boiler houses, both at Ice House Road and at Napier Park House, was completed during the year.

The opening out of the two new streets—one from Wallajah Road through Chetty's Garden to Pycroft's Road in Triplicane, and the other from Wallah's Road, Narasingapuram, to Napier Park—was completed. £4,380 were disbursed to the Deputy Collector on account of compensation and other charges for the acquisition of the properties required, while £763 were recovered from the sale of superstructure of houses. Subsequently, the clearing of the sites, the raising and levelling of the street, and the construction of masonry side drains for the temporary disposal of house drainage along it, pending the laying of the new sewer eventually were done, at an estimated cost of £300 in all.

The construction of the new intercepting sewer at North Beach Road that had been commenced during the previous year, was completed and opened during the year.

The substitution of 24-inch cast iron pipes for a portion of Sewer No. 2, estimated to cost £7,700, was sanctioned by Government during the year, and pipes were imported from England and materials collected for starting the work.

Plans, sections and estimates for the sewers in the 1st, 4th, and 5th Divisions were prepared, the estimates for the 7th Division revised, and these, together with the report as well as the comparative abstract for the whole drainage scheme, were prepared for submission to the Commissioners for sanction.

Besides the above, drains were also constructed in Cemetery Road, 1st Division, and in Gate Street in Mafuskhan Garden, 3rd Division.

Water Supply.—During the year under report 11,813 yards of new pipes were laid, and 66 fountains, 70 valves, 79 stop cocks, 21 hydrants, and 28 meters were fixed. 40,630 feet of pipes were taken up, cleaned, and relaid. This brings the total length taken up, cleaned, and relaid since the commencement of these operations in September, 1900, to 322,166 feet.

On the 1st of April, 1902, the level of the Red Hills Lake stood at 40·36, and on the 31st March, 1903, at 42·89. On the 1st of August, 1902, the level of the lake fell to 35·77, when pumping had to be resorted to for the water supply of the City, and was maintained up to 5th September, 1902, when the level was raised by rainfall and pumping stopped. The lowest level to which the lake fell during the year was 35·49, the level it stood at on the 19th of August, 1902.

The quantity of water supplied to the City during 1902-03 was 594,668,979 cubic feet, against 588,280,185 cubic feet last year.

Private Services.—1,143 new services were laid by licensed plumbers during the year, and 1,951 existing services were extended. The number of new services laid, together with the total up to the end of 1901-02, makes the total of 18,267.

The quantity of water used for non-domestic purposes during the year was 106,108,020 gallons.

Vaccination.—The total number of cases vaccinated during the official year 1902-03 was 32,309, against 38,265 in 1901-02, showing a decrease of 5,956 cases due to the less number of emigrant coolies vaccinated. The results of 32,309 vaccinations performed were 27,054 successful, 2,931 unsuccessful, and 2,324 unknown.

Of the total 26,030 cases vaccinated in the Municipal Vaccine Depôts 7,609 cases were produced at the depôts for inspection of results, and in 18,421 cases the results were ascertained by the respective Division Vaccinators and the parents and guardians who failed to bring the vaccinated children for inspection under Bye-law 5 were warned to take their children to the depôts for the inspection of the Vaccinator. In 160 cases the defaulters were fined to the extent of Rs. 74-12-0 against 200 cases with a fine of Rs. 79-12-0 in 1901-02.

The percentage of success obtained both in primary and re-vaccination, excluding the unknown cases from the total, was 90·34 against 88·05 in 1901-02, showing an increase of 2·29 per cent.

The different kinds of lymph employed in vaccination during the year is given below with the percentage of success obtained in each :—

—	Total cases Vaccinated.	Percentage of Success.
Calf-to-arm vaccination	19,382	94·60
Glycerinated lymph	6,840	98·00
Lanoline vaccine	6,087	67·18

The lanoline paste used in the emigration depôts in vaccinating the emigrant coolies, who were in most cases re-vaccinated, gave a percentage of 67·18 of success against 72·88 per cent. in 1901-02.

Out of 32,309 cases vaccinated 21,898 were primary vaccination against 21,823 in 1901-02, showing an increase of 75 cases with 98·67 per cent. of success or ·29 per cent. below the previous year. The number of re-vaccinations performed amongst adults was 10,411 against 16,442 in 1901-02, showing a decrease of 6,031 cases due to the less number of emigrant coolies vaccinated during the year as compared with 1901-02. The percentage of success obtained in re-vaccination was 69·28 against 70·59 in the previous year.

The number of children vaccinated under one year was 15,092, including 68 cases which were done in the Emigration Depôts against 15,610 in 1901-02, showing a decrease of 518 cases. Of the total 44 were secondary vaccinations. The percentage of success obtained in the infant vaccination was 98·91 against 98·94 in the previous year. Of the total number of children vaccinated 11,293 were born in Madras and 3,799 were born in the moffussil.

During the year small-pox was less prevalent than in 1901-02. Cases of small-pox were also occasionally imported into the city. Infected houses were disinfected by the sanitary staff. Every possible effort was made to induce the relatives to remove small-pox patients from houses in which accommodation was insufficient to the isolation hospitals, and the infected houses were visited by the vaccine staff to vaccinate the unprotected children found in the neighbourhood. Re-vaccination was also encouraged in the infected areas, and those who were willing to undergo the operation were vaccinated.

Vital Statistics.—During the year 1902 there were 17,743 births, exclusive of still-births registered in the city, which is a decrease of 1,129 on the previous year and gives a birth-rate of 34·8 per 1,000 of the population, the birth-rate for 1901 and the average of the ratios for the decade being 37·0 and 40·6 respectively. This decrease may be accounted for by the high price of food and the prevalence of epidemic disease in 1901, both of which seriously affect the health and vigour of the population and therefore its fecundity. Other influencing agents also seemed to have been at work. In comparing the relative proportion of males to females according to the four previous Census returns, it was noticed in the Administration Report for 1900-01 that the female population, once in excess, has steadily declined, and according to the last Census return the male population was in excess of the female population by 5,199. Other things remaining the same, a decrease in the number of females must result in a concomitant decrease in the number of births. Of the 17,743 births, 9,066 were males and 8,677 were females, giving a proportion of 100 female births to every 104·4 male births.

Deaths.—The total number of deaths registered from all causes in the City during the year 1902 was 21,395, which gives a death-rate of 42·0 per thousand of the population per annum. This compares very favourably with those of the two preceding years, which were 55·0 for 1901 and 46·2 for 1900, and is a trifle more than the average of the ratios for the decade, which is 41·8. Of the total deaths, 10,915 were males and 10,480 were females, giving the proportion of 104·1 males to every 100 females. The mortality fell most heavily on infants under one year of age, "60 and over" coming next in order.

Mortality according to Divisions and Wards.—The 1st and 2nd Divisions returned the highest rates with 48·7 each per 1,000 per annum and next in order is 3rd Division with 44·1. Among the wards 1st Division, Centre Ward returned the highest death-rate with 57·1 per 1,000 per annum. Next comes 2nd Division, South, with 53·3 followed by 3rd Division, Centre, with 49·3. If the average of the death ratios of the decade is taken, the same order is preserved, viz., 1st Centre takes the lead with 58·2 per 1,000, 2nd South comes second with 50·7 and 3rd Centre and 2nd North come next bracketted with 43·5. 4th Division returned the lowest death-rate during the year under report, viz., 30·9 per thousand, while the average of the ratios of the decade gives the lowest place to 6th Division, South Ward, with 33·3 per 1,000.

There is no doubt that 1st Division, Centre Ward, has been and is the most unhealthy spot in the whole City. It comprises chiefly the Hutting grounds of Ropegodown Paracherry, Singara-garden, and Tinnevelly Settlement. The 1st of these three is not drained at all with the result that the whole of the hutting ground is practically one mass of sewage. The streets are narrow and are literally used as latrines by children in the day and adults after dusk. Low built mud-walled houses with no proper flooring, in such a dangerously polluted soil, must of necessity affect the death-rate of the place. It is literally a case of "Excrement-sodden earth, excrement-reeking air and excrement-tainted water" and no wonder therefore that it is the home of cholera and other epidemic diseases. What is said of the Ropegodown Paracherry may equally apply to Tinnevelly Settlement and Singara-garden, with the addition that in these two hutting grounds a very filthy trade that of paddy boiling is extensively carried on. The water in which the paddy is soaked is as much if not more offensive than even sewage, and the greater part of it soaks in the ground.

The arrangement of houses in this settlement is peculiar, two rows of rooms are built either side with an open yard in the centre closed in by a wall at either end or by another set of rooms. The open yard is for drying paddy and the row of rooms on one side is let to the paddy pounders, one family occupying each room of less than 500 cubic feet, while the opposite row the owner and his family occupy. One end of the open yard is occupied by earthenware tubs to soak paddy in. Some 50 to 100 persons huddle together in one such house and the insanitary condition of which may be easily imagined. The complete removal of the trade from the place although it would be a great hardship on the settlers seems to be the first step towards effecting an improvement in the condition of the place. The 1st Centre Ward is the most feverish centre in the City in addition to being the haunt of all sorts of epidemic diseases that from time to time occur in the City. Very large part of the population of these 3 hutting grounds—strange as it may seem—still cling on to their wells for their water-supply. 2nd Division, South Ward, is in many respects quite unlike the 1st Centre, although it is almost equally insanitary. The greatest defect of the 2nd Division, South, is the extreme overcrowding, in what may be correctly termed dark dungeons. Less than a third of a square mile in area, 2nd South, has a population of 22,304 people. Most of the houses have but one floor, and the rooms in most houses are almost dark in the day. The streets are in most cases far too narrow and run from north to south effectually shutting off all sea-breeze. The streets running north and south of Rasappa Chetty Street are particularly bad in this respect. The filthy cattle yards of Yadapallium must also contribute to the enhanced death-rate. The streets are provided with open drains, but there is a lot of stagnation of sewage and they are very freely made use of as public latrines. Third Centre and 2nd North approach 2nd South very much in their general arrangements.

Under the Act, the municipality has no power to alter existing buildings and any improvement of the buildings already existing, is therefore at present out of the question. There is provision in the Act to interfere in the case of overcrowding, but so long as no provision is made for housing the poor either by the municipality or by private enterprise, no permanent good can result from enforcing the Act, as it will only drive people from

one tenement house to another. The question of widening and opening cross streets must sooner or later receive the attention of the Commissioners.

Cholera.—Total number of deaths from this disease was 37 of which 24 occurred in January, February and March as a fragment of the outbreak of 1901. The remaining 13 cases were either sporadic or imported, the latter counting the majority.

Small-pox.—The total number of deaths from this disease during the year 1902 was 69 against 292 in the year previous.

Fever.—This heading conveys practically no information, as the number of diseases in which fever is a prominent symptom is large and varied, 7,326 deaths were returned as due to fever, against 9,151 last year but it is more than the average of the decade which is 6,129. It is not possible to say anything more than repeat what has been said in the reports of previous years, viz., that so long as registration remains in its present defective condition, no opinion as to the real causes that led to this high mortality is possible. Malarial fever and phthisis no doubt contributed largely to the total, but pleurisy, pneumonia, typhoid, rheumatic fever, affections of the liver, &c., added their quota. Among the other diseases attended with fever, dengue, a disease which was epidemic in the City from April to October appears to have contributed to this increase. Although ordinarily attended with very little fatality, dengue is not altogether without casualty especially in the weak, aged and young, and more so when through unskilful management or imprudence complications set in. It is not therefore unreasonable to suppose that a disease which laid its burden on almost every one, contributed, even a little, to the mortality of the town. The actual number of deaths registered from dengue are only few. Dengue made its appearance last time in the City in 1872 and now after a lapse of thirty years it again made its appearance about the beginning of the year. The disease appears to have been imported into the City from Burmah where it prevailed in a severe form. A disease peculiar to hot climates, dengue always spreads in the hot months and dies out with the onset of the monsoon and the cold weather. Practically very little was heard of the disease after the beginning of November. A few cases of the disease known as epidemic dropsy were also reported during the year. With regard to prevalence of fever in the different parts of the City—2nd Centre returned highest rates during the year under report and 1st Centre comes next. If the average of the ten previous years be taken 1st Centre stands far ahead of the rest.

Bowel-complaints.—There were 2,789 deaths from dysentery and 572 from diarrhœa against 4,099 and 771 respectively in the year previous. The ratio of deaths from dysentery was 5·4, from diarrhœa 1·1 against 8·0 and 1·5 respectively in the previous year.

Infantile Mortality.—The death-rate among infants under one year of age was 303·9 per 1,000 births against 328·3 of the preceding year and the ratio calculated on the infantile population was 395·1 against 454·0 of the previous year. This ratio although better than last year is still very high and the general ignorance with regard to the management of births and babies and a lack of all knowledge of infant hygiene, together with insanitary conditions which obtain in the City, account for this high rate being kept up.

Plague Measures.—The services of the Plague Officer were dispensed with at the beginning of the official year, and to supervise the Passport Staff, the Special Sanitary Inspector on Plague duty was appointed Superintendent of Passports. The number of persons detained during the year at the several Plague Camps in the City was :—At Perambur, 3,119 ; at Washermanpet, 179 ; and at Egmore Plague Hospital, 208. 13 cases of plague occurred in the City during the year—all of which were imported. Of these 10 were removed and treated in the Egmore Plague Hospital and the other 3 died at their residences. Of the 10 cases treated in the Hospital, 3 recovered. Of the 13 cases, 6 were imported from Adoni and 3 from Kolar District.

The total number of passports issued at Perambur during the year was 68,471 against 55,120 in the year previous. The excess was chiefly due to the large increase in the number of notified places. The number of passport holders untraced was 1,065 against 1,224 in the previous year giving a precentage of 1·65 against 2·44. The number

of moffussil passports received was 11,017 against 8,079 of the preceding year. Of these 11,017—512 could not be traced giving a percentage of 4·64. The percentage of the untraced last year was 6·39.

The attendance of passport holders was satisfactory. Amongst 64,212 passport holders there were only 164 prosecutions and 112 convictions against 50,171 passport holders, 339 prosecutions and 178 convictions last year. The fines inflicted amounted to Rs. 386 against Rs. 591-12-0 in the year previous.

The Port Health Officer reports as follows with regard to the plague inspection of vessels :—318 vessels, departures from Madras, carrying a crew of 27,783 persons and 31,844 passengers were inspected during the official year 1902-1903 and granted Bill of Health. The inspection of the crews and passengers was carried out on shore. Besides these, 186 vessels, arrivals from plague infected ports, and carrying a crew of 13,624 men and 2,620 passengers for Madras were inspected on Board before communication between the vessels and shore was permitted. All passengers landing at this port are granted plague passports. On board these 186 vessels 11,600 shore coolies worked. Before being sent on board the names and addresses of the coolies are taken down and on their return in the evening they are given a disinfecting bath of perchloride of mercury. Such coolies as are absent on the following morning are inspected at their homes under the orders of the Municipal Health Officer.

ABSTRACT OF THE REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR 1902-03.

(W. L. Harvey, Esq., C.I.E., Municipal Commissioner.)

PUBLIC WORKS.—*Drainage.*—The machinery at the Colaba Compressor Station and the several Ejector Stations worked satisfactorily during the year.

The engines and pumps at the Love Grove Pumping Station worked satisfactorily during the first half of the year. In the month of October, however, it was discovered that the efficiency of the pumps had fallen considerably, and that they were not capable of keeping down the sewage in the main sewer to the usual level. Steps were immediately taken to set the matter right.

The street portions of house-drainage connections carried out departmentally numbered 530 at a cost of £1,946.

Several latrines and urinals have been constructed at different places to meet the public convenience.

Works in connection with the sanitary arrangements of the various Health Camps, Observation Camps and Plague Hospitals were carried out by the Drainage Department, Ordinary Branch.

Several works executed by the Drainage Department, Special and Ordinary Branches, have been detailed in the Executive Engineer's report.

WATER WORKS.—*Tansa Lake.*—The rainfall for 1902 was 89·87 inches against 96·15 inches for 1901. The total quantity of water received in the lake was 34,531 millions of gallons or 50·4 per cent. of the rainfall on the catchment area of 52·5 square miles.

Vehar Lake.—The rainfall for the year 1902 was 72·92 inches against 75·58 inches during the preceding year. The total quantity of rain which fell on the whole of the drainage area of 3,900 acres was about 6,483 millions of gallons, of which about 5,335 millions of gallons or about 83 per cent. of the total rainfall reached the lake. There were 4 bursts on the 32″-main between Curry Road and Mátungá, and 2 bursts north of the Coorla Station.

Tulsi Lake.—The rainfall for 1902 was 93·19 inches against 93·62 inches for 1901. The total quantity of rainfall on the whole drainage area of 1,700 acres was 3,623 millions of gallons, of which about 1,810 millions of gallons reached the lake—this is about 50 per cent. of the total rainfall. There was 1 burst near Marole in the Tulsi 24″-main.

Supply and Distribution.—One 9″-main has been laid as an additional supply main in the De Lisle Road from its junction with Carrol Road and a 4″-main, about 1,200 feet in length, has been laid in the Wodehouse Bridge Road. There were 116 bursts in various mains, of which 42 were caused by the operations of the drainage contractors. 405 new connections were made, and 274 connections were cut off for various reasons. The total number of connections at the end of the year was 20,683, and the number of meters in use was 3,202.

Public Health.—The state of the public health during the year was better than in the preceding year, the number of deaths, exclusive of still-born, being 48,414 against 59,495 for the previous year. There were 13,820 deaths from plague against 18,736 during 1901. The number of births registered during the year was 17,599, being 4,079 more than in the past year.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1902.

(*Dr. John A. Turner.*)

Births.—The number of births registered during the year was 17,599, being 4,079 more than in the previous year and 6,209 more than the average of the preceding five years, giving a birth-rate of 22·67 per 1,000 of population against 17·42 during the corresponding period of the last year ; of the total number of births 9,154 were males and 8,445 females, and 2,017 still-born births. From this it will be seen that there was a marked improvement in the registration of births. The birth-rate amongst Parsees was 24·55 and amongst Europeans 11·81 as against 24·65 and 11·97 respectively during the last year.

Mortality.—The number of deaths in the City of Bombay during the year 1902, exclusive of still-born, was 48,414, being 11,081 less than in 1901 and 10,613 less than the average for the past five years, giving an annual death-rate of 62·38 per 1,000 of the population.

The mortality during the year under report was the lowest of the previous corresponding period of any year since 1898 as shown below :—

Years.	Total number of deaths.
1898	51,961
1899	56,434
1900	79,350
1901	59,495
1902	48,414

Plague.—During the year the control of all plague measures was under the Health Department. The mortality from plague began its seasonal rise in January and reached its maximum on the 3rd of April and then declined. There were 16,423 attacks and 13,820 deaths from plague during the year as against 21,006 attacks and 18,736 deaths during the last year. As in previous years the general Hindu community suffered severely from plague, the mortality amongst this class being 8,597 as against 12,418 during the last year. There was a decrease in the number of deaths from plague in all the communities except Europeans and Negro-Africans, who show 13 and 9 cases as against 10 and 6 respectively during the last year. There was a marked reduction in the number of deaths from plague in all the sections of the City except Upper Colaba, Fort, Southern and Chaupati.

A total of 9,159 deaths took place amongst males and 4,661 amongst females as against 12,611 and 6,125 respectively during the last year.

The highest plague mortality was recorded in the month of March, the number being 3,609, April coming next with 2,800 ; the lowest mortality was in July, 129 deaths being recorded. From August the plague mortality rose gradually to the end of the year, 570 deaths being recorded in December, 1902. The plague mortality was highest on the 3rd of April, 148 deaths being registered on that date, while on the 30th of March the highest daily mortality for the year was recorded, viz., 287.

Causes of deaths compared.—In the following table it will be observed that there has been a marked decrease in the number of deaths from all diseases except small-pox and measles, which stood higher amongst them as compared with the figures of the previous year.

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM DIFFERENT CAUSES IN 1901 AND 1902.

Cause of Death.	1901.		1902.	
	Number of Deaths.	Death-rate per 1,000 of Population according to the Census of 1901.	Number of Deaths.	Death-rate per 1,000 of Population according to the Census of 1901.
Small-pox	159	·20	288	·37
Measles	67	·08	642	·82
Fevers	7,921	10·20	4,518	5·82
Cholera	198	·25	75	·09
Plague	18,736	24·14	13,820	17·80
Phthisis	6,516	8·39	3,957	5·09
Diseases of the Nervous System	2,971	3·82	3,027	3·90
„ Respiratory System	7,804	10·05	7,250	9·34
Diarrhœa	2,375	3·06	2,266	2·92
Dysentery	1,341	1·72	1,377	1·77
Accidents	764	·98	732	·94
All other Causes except Still-born	10,643	13·71	10,462	13·48
Total	59,495	76·66	48,414	62·38

By sexes, 27,826 males and 20,588 females died during the year. The highest number of deaths amongst males occurred in the age-period between 25 to 30 years, 3,222 deaths having been registered, and amongst females 2,034 in the age-period of 15 to 20. The lowest number of deaths amongst males occurred in the age-period between 4 to 5 years, 235 deaths having been registered, and amongst females 246 in the age-period of 3 to 4 years.

The death-rate by classes.—The death-rate by classes is shown in the following table. It will be seen from this that the Jain community, which includes Banias, excepting Negro-Africans, Buddhists, and Lingaets, who form very small communities, show the highest mortality, viz., 137·14 per 1,000 of population. Next comes Hindus, low-caste, the death-rate being 75·59. The general mass of the Hindu Community give a death-rate of 63·03 and Mussalman 65·82. The death-rate amongst Parsees was 30·41, European death-rate being more than the last year, viz., 21·99 as against 15·39 during the last year.

Small-pox.—Two hundred and eighty-eight deaths from small-pox occurred during the year, as compared with 159 in 1901 and 746 during the average of the preceding five years. The disease did not assume an epidemic form until late in the year. It was brought to my notice that a large number of unvaccinated people from the Portuguese territories, especially from Goa, were coming to Bombay, and most of them, soon after their arrival here, were found suffering from small-pox, and thereby spreading the disease in the city. I then addressed a letter to the Consul-General for Portugal, enquiring whether vaccination is compulsory in the Portuguese towns, especially in Goa, and in reply he sent me a copy of the letter received by him from the Chief Secretary of the Government of Goa, that, according to Government Resolutions dated 11th February, 1883, and 24th July, 1896, vaccination is compulsory, but there is no restriction on those who leave the country, and that they are not subject to special observations. I also addressed a letter to the Municipal Commissioner, bringing to his notice the prevalence of small-pox among the Goanese in Bombay. Handbills in Gujarathi and Marathi for the prevention of the spread of small-pox in the city were distributed to the public.

Cholera.—From cholera 75 deaths were registered during the year, as compared with 198 in 1901 and 1,190 during the corresponding year of the last five years. The disease did not assume an epidemic form. The highest number of deaths from this disease was registered in the month of March. Of the total number of deaths, 47 occurred amongst Hindus of other castes, as against 131 during the last year ; 13 amongst Mussalman, as against 18 during the last year. Eighteen deaths occurred amongst persons who had resided in Bombay for three months and under, and eight deaths amongst those who resided in Bombay for six months and under. Out of the total of 75 deaths, 65 occurred amongst persons born outside of Bombay.

Fevers.—A total of 4,518 deaths was registered from fevers. Remittent fever claims the highest number, viz., 3,847, being 3,419 less than in the last year, and 1,938 less than the average of the preceding five years. To simple continued fever 99 deaths were registered, being 14 less than in the last year, and 171 less than the average of the previous five years. To enteric fever 89 deaths were ascribed, being 27 more than the last year, and 42 more than the average of the last five years. To ague 483 deaths were registered, being three more than the last year, and 190 more than the average of the last five years. It will be observed that the fever mortality rose and fell with the mortality from plague. It commenced rising from January to March, when the highest number of deaths, viz., 868, was registered. The highest number of deaths from plague registered in the month of March was 3,609. From the month of April fever gradually decreased till the end of the year.

Excluding Jains, which form a very small community, there was a slight increase amongst Lingaets, Bhatias, Europeans, Eurasians, and Negro-Africans, the rate being 5·59, 6·12, 4·39, 4·60, and 4·79 respectively, as against 3·26, 3·54, 2·60, 2·14, and 1·59 respectively in the previous year. The general mass of Hindu community show a very remarkable decrease, the rate being 6·02, as against 13·42 in the previous year. Mussalman give a death-rate of 5·21 as against 6·60 in the last year.

During the year investigations into the prevalence of malarial fever were made, and report submitted to the Corporation. The divisional health officers instructed their staff into the methods of distinguishing the various mosquitoes and larvæ, and a list of places was made out where anopheles larvæ were found.

To relapsing fever 651 deaths were ascribed, being 909 less than in the last year, and 167 less than the average of the preceding five years. The highest number of deaths from relapsing fever was registered in the month of February, when 103 deaths were registered. From March the disease gradually decreased till the end of the year.

Measles.—From measles 642 deaths were registered during the year, being 575 more than the last year and 228 less than the average of the preceding five years. The disease prevailed in an epidemic form during the last two months of the year.

Phthisis.—From phthisis 3,957 deaths were registered during the year, being 2,559 less than the last year, and 2,502 less than the average of the last five years. The most fatal period of life amongst males was between the ages of 25 to 30, and that of females between the ages of 20 to 25. The female death-rate was more than double that of male. Leaving out Negro-Africans, which is a small and fluctuating community, the mortality from this disease was high amongst Jains, but less than the last year, the rate being 11·22, as against 18·80 in the last year. There is a decrease in the number of deaths amongst Mussalman, the rate being 8·52, as against 13·89 in the last year.

Infant Mortality.—The number of deaths amongst children under one year of age was 9,553, being 1,785 more than in the previous year ; of these, 8,399 deaths took place amongst the children born in Bombay, and 1,154 amongst those born out of Bombay. The number of births registered during the year was 17,599, giving an infant mortality of 537·13 per 1,000 of the births. Small-pox and measles accounted for 87 and 205 deaths of infants under one year of age respectively. Diseases of the respiratory system are stated as being responsible for 2,347 deaths amongst infants under one year of age, as against 1,536 in the last year, while under the head of "diarrhœa" 617 deaths are given, as against 484 in the last year. The other causes given are :—Diseases of the Nervous System "Convulsions" (2,023), and debility (3,025) ; of the latter, 2 232 deaths were under 30 days.

General.—From diseases of the digestive system, 4,744 deaths were registered, being 128 less than in the last year, and 1,293 less than the average of the preceding five years ; of these, 2,266 were ascribed to diarrhœa, being 109 less than in the last year,

and 619 less than the average of the last five years. To dysentery, 1,377 deaths were registered, being 36 more than in the last year, but 461 less than the average. To all other diseases of the digestive system, 1,101 deaths were registered, being 55 less than in the last year, and 213 less than the average.

Nervous Diseases.—To diseases of the nervous system, 3,027 deaths were registered, being 56 more than in the last year, and 21 more than the average. Out of the above number, 2,314 deaths were due to infantile convulsions.

Respiratory Diseases.—From diseases of the respiratory system, 7,250 deaths were registered, being 554 less than in the last year, and 213 less than the average; of these, 4,001 deaths were referred to bronchitis and 1,867 to pneumonia.

Circulatory Diseases.—To diseases of the circulatory system, 364 deaths were referred, being 67 more than in the last year, and 48 more than the average.

APPENDIX.

No. 1.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER with the GOVERNMENT of INDIA, for 1902.

The brief sketch given of its chief meteorological features shows 1902 to have been a comparatively dry year, the rainfall for India, as a whole, having been somewhat less than the annual mean. Accompanying this dryness, there was a decrease in the prevalence of malarial fevers amongst the troops and prisoners. Over the greater part of India the temperature of the year was above normal, a condition accompanied by an increase in the number of admissions and deaths from heat-stroke amongst the European troops as compared with that recorded in the previous year.

2. The average strength of the European Army of India has varied but slightly during the past three years. In the year under report it was 60,540. The health of the troops is described in the Army Medical Department Report as having been exceptionally good; but the death-rate rose from 12·38 in 1901 to 14·68 in the year under report. The disease which contributed more than any other to this increase was enteric fever. From 3·32 per thousand of average strength in 1901, the death-rate from this cause rose to 4·29. Abscess of the liver and pneumonia were also more fatal than in 1901. Between them, enteric fever and abscess of the liver caused 41·8 per cent. of the deaths from all causes as compared with 37·8 per cent. in the previous year. Although the death-rate was considerably higher, the admission-rate, the constantly-sick-rate, and the invaliding-rate were all lower than in 1901. As usual, intermittent fever and venereal diseases were the chief causes of admissions, the former accounting for 22·9 per cent., and the latter for 26·0 per cent. of the admissions from all causes. In the previous year, intermittent fever was responsible for 26·5 per cent., and venereal diseases for 24·9 per cent., of the admissions, showing that whilst the former was considerably less prevalent, the latter was somewhat more prevalent in the year under report. These two diseases, although the cause of so high a proportion of the admissions, had comparatively few deaths directly ascribed to them, ague being credited with 30 and secondary syphilis with 15 deaths out of a total of 889 for the year. Together with debility, they were the cause of 810 of a total of 2,255 invalidings.

3. Of the four Commands, Bombay was the most unhealthy, with a death-rate of 19·58 per thousand of strength, as compared with a death-rate of only 8·92 in Madras, the healthiest Command. To the high death-rate in the Bombay Command, enteric fever contributed no less than 5·69 and circulatory diseases 2·57; these two diseases accounting, respectively, for 1·71 and ·54 in the Madras Command. But with, by far, the lowest death-rate, Madras recorded a higher admission rate than any of the other Commands excepting Bombay. This was chiefly due to the comparatively greater prevalence of venereal diseases in the Madras Command.

4. Of the chief diseases, *influenza* and *cholera* showed a much diminished prevalence in the European Army, the admissions from the former having fallen from a ratio of 8·9 per 1000 the previous year, to 1·8 with only one death; whilst of cholera there were only three cases, all of them fatal. The decrease in the prevalence of cholera was not confined to the European Army, but extended also to the Native Army, to the prisoners, and to the general population. Whilst the ratio of deaths from cholera was ·05 per thousand in the European Army, it was 0·12 in the Native Army, 0·21 amongst the prisoners, and 1·01 amongst the general population. In the great cholera epidemic year of 1900, the death-rate in the European Army was 1·45, in the Native Army 3·16, amongst the prisoners 2·28, and amongst the general population 3·7. These figures appear to show that a rise or fall in the general prevalence of cholera affects all classes of the population, European and Native. In the year under report, the European Army suffered proportionately less in comparison with the rest of the population of the country than it did in 1900. This may be taken as an indication of the more rapid progress of sanitation as applied to the prevention of disease amongst European troops, than amongst the rest of the population. The epidemics of cholera, which, in the not remote past, proved so destructive of life in the European and Native Armies, still continue to carry off large numbers of the general population. If it were practicable to apply them, there is no reason to doubt that the measures which have proved successful in preventing the recurrence of these epidemics amongst the troops, would be found equally successful in preventing them in the case of the general population.

5. It is contrary to what might have been expected to find *small-pox* more fatal in the European than in the Native Army. In the former, 23 attacks with four deaths were recorded; whilst in the latter, although 75 men were attacked, there were only two deaths. Moreover, the Native was more than double the numerical strength of the European Army. It is stated with regard to the European soldier who died of small-pox at Meerut that he had been twice vaccinated, the last time in 1898; but it is not mentioned if the latter operation was successful.

6. There was a marked decrease in the prevalence of *intermittent fever*, the ratio of admissions falling from 293·2 in the previous year, to 247·1 per thousand of strength in the year under report. It is stated that in nearly all the stations in which a decrease in the admission rate on account of ague occurred, the medical officers attribute the decrease partly, or wholly, to measures taken to prevent the breeding of *anopheles* mosquitoes by applying kerosene oil to pools and other collections of water. But it is pointed out by the Sanitary Commissioner with the Government of India that a decrease in the

prevalence of intermittent fever during the year under report was noted in the majority of stations throughout India, and not only amongst British troops, but amongst Native troops and prisoners as well. The experiment, commenced in April, 1902, and carefully carried out under expert supervision at Mian-Mir, does not encourage the hope that operations having for their object the destruction of mosquitoes will be effectual in putting an end to, or even materially diminishing, malarial fevers. The report on the anti-malarial operations at Mian-Mir, 1901–03, ends :—"Moreover, it appears to us "that gradual but permanent improvement in the health of stations by well directed sanitary reforms, "wherever these can be carried out, will in the end yield the best return."

7. The steady decrease in the mortality from *enteric fever* in the European Army of India, which has been taking place from year to year since 1898, has at length received a check. In the year mentioned, the death-rate reached by this disease was no less than 10·17 per thousand of strength ; from which high rate it fell to nearly half in the following year, and more slowly in 1900, until in 1901 it was only 3·32. The decrease was believed to be due mainly, if not wholly, to the lessened influx of young soldiers from England during the continuance of the Boer war. This belief seems to be confirmed by the increase which began to take place in the death-rate from enteric fever when the despatch to India of the usual annual drafts was resumed. From 3·32 in the previous year, the ratio of deaths per thousand of strength has already risen to 4·29 in the year under report. An examination of the tables on page 34 of the Appendix to the Report, shows that in 1898, when the enteric death-rate was 10·17 per thousand of strength, 54 per cent. of the soldiers were under 25 years of age, and 81 per cent. of them had been in India less than five years ; whilst in 1901, when the death-rate had fallen to 3·32 per thousand of strength, only 42 per cent. were under 25 years of age, and 63 per cent. of them less than five years in India. In the year under report, when the enteric fever death-rate has begun again to rise, the number of men who arrived from England has risen from 18,594 in the preceeding year, to 24,840 ; whilst at the same time, the percentage of men under 25 years shows a slight decrease, and that of men of less than 25 years of residence in India an increase from 63 to 68. The Report gives, as usual, an excellent *résumé* of the progress of research into the nature or entity of enteric fever and its etiology. The perusal of another year's record of scientific investigation tends to suggest the need for caution in accepting some of the conclusions hitherto regarded as permanently established on a secure basis. The "solely waterborne" theory of the causation of enteric fever is held by a diminishing number of observers. "That enteric fever is frequently communicated by direct "infection from one case to another is now recognised on all sides." Koch considers this to be perhaps the most important of all methods by which typhoid fever is disseminated. In his successful campaign against the disease at Treves he found that all the cases were to be referred to contact ; the "infection was always carried directly from one person to another and no trace of a connection with "water was to be found." The detection of the bacillus in water is now acknowledged to be a matter of extreme difficulty. In last year's *memorandum* it was noted that Sims Woodhead had only once been able to isolate the bacillus from water, and in that case he had placed it there himself. After much experience, Koch states that in his recollection he has only once been able to prove the presence of the bacillus in a suspected water. The infallibility of the Widal reaction as a test in the diagnosis of enteric fever is called in question by several observers. It is said often to fail in mild cases, or to make its appearance too late in the course of the disease to be more than an aid to diagnosis. "The "fact that no cases were returned as enteric fever unless they gave the Widal reaction, is assigned as a "reason for the decrease of the number of cases at Mhow and some other stations. At Mhow, although "for this reason the number of admissions was about half that of the previous year, the death-rate was "nearly double ; and the medical officer considers that in 1901 a number of cases were wrongly "diagnosed as enteric fever—the small percentage of deaths and the monthly distribution pointing to "this." Such instances indicate the uncertainty which still prevails in the diagnosis of enteric fever and may help to explain some of the wide differences in the ratios of admissions, and in the percentage of deaths to admissions, disclosed by the returns in certain stations and hospitals.

8. The resumption of the despatch to India of the usual annual drafts of troops, which had been interrupted during the war in South Africa, appears to have affected the prevalence of *venereal disease* in the same way as that of enteric fever. The steady decrease in the ratio of admissions from venereal disease from 522·3 per thousand of strength in 1895, to 276·0 in 1901, not only received a check but was replaced by a slight increase in the year under report, when it rose to 281·4. The admission-rate was much above the average for the European Army as a whole, in the Madras Command, and much below it in the Punjab Command, having been in the former 343·4, in the latter 217·5. Yet the rate for the Madras Command is considerably below that recorded in 1901, when it was 372·8. In Cannanore the rate rose to no less than 689·2 per thousand ; but the average strength of the garrison was only 74. The increase at this station was attributed by the medical officer to the absence of any restriction with regard to prostitution, and to there being no cantonment hospital where diseased women can be treated—a description of local conditions, with their attendant consequences, which might not be unworthy the consideration of those who advocate the abolition of all measures specially designed for the protection of the soldier against venereal diseases.

9. Excepting *abscess of liver*, none of the other diseases were unusually prevalent or fatal. Although wide-spread and fatal amongst the general population, *plague* attacked but four European soldiers during the year, and of these only one died. Abscess of the liver accounted for 112 deaths, as compared with 83 in the previous year. At some stations the disease was the cause of high ratios of admissions and mortality. In the garrison at Barrackpore, with an average strength of 343, there were 18 admissions with 10 deaths from hepatic abscess. "The medical officer states that most of the men who died from abscess of the liver were said to be heavy drinkers."

10. The average annual strength of the *Native Army* during the year under report was 124,231, or somewhat greater than during the previous year. Its health was good, although, as in the case of the European Army, there was some increase in the death-rate, which was 11·16 per thousand, as compared with 10·68 in 1901. The disease which caused by far the highest percentage of total deaths was again *pneumonia*. To this were ascribed 33·2 per cent. of the total mortality for the year. If

to deaths from pneumonia are added those from *tubercle of the lungs* and *other respiratory diseases*, the combined percentages of deaths due to them mount to 43·5 of every hundred from all causes. The contrast between the European and Native Armies of India in respect of the incidence and fatality of respiratory affections is striking. Whilst in the former these were accountable for a percentage of only 12·4 of every hundred deaths, in the latter they were accountable for a percentage of 43·5. These figures seem to suggest the nature of the sanitary improvements calculated to lessen the prevalence of the diseases to which mortality amongst the Native troops is in great part due. If to the diseases mentioned are added *remittent* and *intermittent fevers*, which together accounted for a percentage of 18·2 in every hundred deaths, no other one disease was credited with a higher percentage of deaths than 3·5.

11. In both the Native and European Armies *intermittent fever* contributed, as usual, a large proportion of the admissions into hospital. In the former this amounted to 274·5 of a total admission-rate of 718·0. To the prevalence of *venereal diseases* amongst the European troops was mainly due the wide divergence between the admission-rates in the two armies. In the European Army these diseases accounted for an admission-rate of 281·4 per thousand of strength, and in the Native Army for only 32·8. Had the European troops suffered from venereal diseases in the same proportion only as the Native troops, the admission-rate for the former would have been, not 1,078·4, but 829·8, as compared with 718 for the latter.

12. *Cholera* was again in comparative abeyance in the Native as well as in the European Army. There were only 26 cases with 15 deaths, as compared with 35 cases and 19 deaths in the preceding year. *Enteric fever* was credited with having been the cause of 50 admissions with 12 deaths, as compared with 24 admissions and 15 deaths in the previous year. The difference between the ratios of deaths to admissions for each of the two years is striking, and would suggest either a much milder type of the disease or, what is more probable, greater, or less, accuracy in the diagnosis of cases recorded as enteric fever. The contrast between the European as compared with the Native soldier in liability to die from enteric fever continues to be as marked as ever: whilst the death-rate ascribed to enteric fever was 0·10 in the Native Army, it was 4·29, or more than forty times greater, in the European Army. A further decrease in the prevalence of *venereal diseases* is recorded in the Native Army. The ratio of admissions, which had risen to 42·5 in 1900, fell in 1901 to 34·3, and now in the year under report, still further to 32·8 per thousand of strength, as against 281·4 in the European Army. *Abscess of the liver* is another disease from which the Native soldier is comparatively exempt. Whilst amongst the Native troops there were only 13 admissions with eight deaths from abscess of the liver, there were 198 admissions with 112 deaths from this cause amongst the European soldiers, although the average numerical strength of the latter was less than half that of the former. *Dysentery* and *diarrhœa* were both somewhat more prevalent amongst the Native troops than in the previous year. Whilst, as already mentioned, there were only four cases of *plague* with a single death amongst the European troops, there were amongst the Native troops 192 cases with 95 deaths. The greatest number of cases occurred amongst the troops stationed at Bangalore. Of 33 cases occurring in one regiment at that place, 14 had been inoculated, and of these six recovered, five died and three remained under treatment at the end of the year. Of the remaining 19 uninoculated cases, three recovered, 14 died, and two remained under treatment at the end of the year. If these figures may be taken as a measure of the prophylactic effects of anti-plague inoculation generally, they can scarcely be regarded as affording much encouragement to those who would trust to it alone for stamping out the disease.

13. The average number of *prisoners* in jail, which had been 121,812 in 1900, and 117,203 in the following year, fell in the year under report to 114,334. This decrease of the jail population may be taken to indicate that more prosperous times have been succeeding seasons of scarcity and famine. In accordance with what was to be expected, the return of prosperity was accompanied not only by a decrease in the number of prisoners, but by an improvement in their health. The climatic conditions of the year, which was hot and rather dry, were also, on the whole, favourable to health. The jail death-rate, which had been 34·27 in 1900, fell to 26·59 in the following year, and still further in the year under report to 24·61. Of the chief diseases *cholera*, as in the case of the troops and general population, was less fatal amongst the prisoners than in the previous year, the number of deaths ascribed to it falling to 24 from 103. Regarding the outbreaks amongst the prisoners at Benares and Ghazipur, it is stated that their origin could not be traced; but at both places the free population was suffering from cholera at the time when the disease appeared in the jails. This is still the usual experience throughout India. *Enteric fever* was less fatal than in the previous year, the number of cases decreasing from 20 in 1901 to 15 in the year under report. At the same time the admissions ascribed to enteric fever increased from 41 in the former year to 69 in the latter;—figures which might suggest change in the type, or treatment of the disease, but may rather have been due to change in methods of diagnosis. In any case, the records show that enteric fever is productive of a share of the mortality in the Native Army and jails which is insignificant when compared with that of which it is the cause in the European Army of India. The chief causes of mortality in jails were, as usual, *dysentery* and *diarrhœa*, *tubercle of the lungs* and *pneumonia*. To these were due 57 out of every 100 deaths amongst the prisoners during the year under Report. Repeating a remark in a former Report by the Sanitary Commissioner with the Government of India:—"The heads of jail mortality requiring special "attention are bowel complaints, tubercle of the lungs, and respiratory diseases." Taking into account the widespread prevalence of *plague* amongst the general population, the occurrence of only 37 cases with 20 deaths testifies to the success of the measures adopted to exclude the disease from the jails. *Cerebrospinal fever* was accountable for 108 deaths, as against 102 in the previous year. The number of cases of the disease at the same time decreased from 141 in the previous year to 130 in the year under report. The serious increase of cerebrospinal fever noted in the preceding year has not, therefore, continued. The existence of this form of fever amongst the free population is said now to be acknowledged; and measures are taken by the medical officers to prevent infection from being imported into the jails under their charge.

1st October, 1904.

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bengal for 1902.

Although Major Clarkson, I.M.S., writes the Report, he was in charge of the duties of Sanitary Commissioner during no part of the year with which it deals. The first two and the last two and a half months of the year were almost rainless, the Orissa Division alone receiving its normal amount of rain in January. On the other hand, the rainfall was nearly everywhere in excess in July, and much in excess in North Bengal during August and September; whilst Bihar suffered from a deficiency in August, and from an excess in September. The Sanitary Commissioner thinks "the "scanty rainfall during October, by failing to wash away surface impurities and flush out filthy tanks "and ditches prior to the cessation of the rains, rendered the last quarter of the year generally "unhealthy." Deficient and unseasonably distributed rainfall was unfavourable to the crops, but "the average prices of staple grains were more or less lower than in the preceding year in almost "every district."

2. A *birth-rate* of 40·14 per thousand of population is recorded for the year under review, as compared with 38·57 in the preceding year. This probably falls but little short of the true rate, and is a fresh proof of the remarkable progress which has taken place in birth registration in Bengal since 1892, prior to which it was limited to municipal towns. The Inspectors and Sub-Inspectors of Vaccination report that, of 305,986 births which they were able to verify during the year, only 2,617, or ·85 per cent., remained unrecorded in the police registers. The birth-rate recorded in towns is in marked contrast with that recorded in rural areas: whilst in the former it was only 24·95, in the latter it was 40·93 per thousand of population. In last year's *Memorandum* on the Sanitary Report for the Madras Presidency it was noted that the relation of the town to the country birth-rate there recorded was reversed, the urban being higher than the rural rate. Reasons were given for suggesting that this abnormal relation between the urban and rural birth-rates recorded in Madras might be the result of defective registration. Some estimate may be formed of the fecundity of the population of the Province of Bengal from the statement made by the Sanitary Commissioner, in paragraph 11 of his Report, to the effect that 148 rural areas returned birth-rates of upwards of 45 per thousand of population. "This," he remarks, "was fairly satisfactory and was no doubt due to the general healthiness of the year 1901." When, however, reference is made to Annual Form No. IV. of the Appendix to the Report, and it is seen that male infants died at the rate of 301·80, and female infants at the rate of 254·05 per thousand of population, this satisfaction is liable to undergo some modification, and the idea suggests itself that a lamentable waste of life results from the introduction into existence of more children than their parents have the means of rearing. Perhaps the permeation of the population with knowledge may be followed in Bengal, as in Western countries, by a decrease of the birth-rate. In Great Britain this has already fallen below 29 per thousand of population, and continues to fall. The decreasing birth-rate, as might be expected, is accompanied by a decreasing death-rate.

3. The *death-rate* for 1902 increased from 31·04 in the preceding year to 33·43. This increase, the Sanitary Commissioner says, was chiefly due to the greater unhealthiness of the year. Such was probably the case; but the increase of the birth-rate from 38·57 in the previous year to 40·14 in the year under review, cannot be dissociated from the synchronous increase of the death-rate, which it undoubtedly influenced. Fever, cholera, and small-pox were all more fatal than in 1901. The mortality in urban exceeded the mortality in rural areas in the proportion of 35·98 in the former to 33·30 in the latter. The Sanitary Commissioner writes: "It will be seen that the incidence of "cholera, dysentery, and diarrhœa, and the diseases grouped under the heading 'other diseases' was, as "usual, higher in towns than in rural areas, while fever continued to show a great preference to the "latter as its favourite abode." It might be suggested, however, that this marked difference in the incidence of these diseases may be due in great part to difference of diagnosis. It seems probable that the more intelligent inhabitants of towns would succeed better in differentiating the causes of death than the less intelligent inhabitants of rural areas. The latter would appear to lump under the head of "fever," deaths which the former attribute to plague, dysentery, and diarrhœa, respiratory diseases, and "other causes." A study of the return given in paragraph 16 of the Report seems to lend support to such an explanation of the contrast between the chief causes of mortality recorded in towns and those recorded in rural areas.

4. Of the *chief diseases*, all, with the exception of plague, were more fatal than during the preceding year. The death-rate of 1·48 per thousand of population, due to cholera in 1901, increased to 2·02 in the year under report: but the course which the disease ran appears to have differed little from that annually recorded. Outbreaks are, as usual, generally concluded to have had their origin in polluted water-supplies. This being so, the means adopted with the object of cutting short these outbreaks have naturally resolved themselves into measures for the purification of those supplies. During cholera epidemics tanks and wells that are resorted to for drinking purposes were disinfected "with permanganate of potassium. "In most cases no systematic record of result was kept, as the "disinfection has to be generally done by non-medical men; but it is generally said to be attended with beneficial results." In previous *memoranda* the need for submitting the results of the treatment of wells and tanks with permanganate of potash to exact scientific examination has been insisted on. The quotation just given from the Sanitary Report may be taken as an example of the inconclusive nature of the evidence upon which belief in the efficacy of permanganate of potash in cutting short cholera outbreaks, usually rests.

5. *Small-pox*, which has been increasing in fatality since 1899, was credited with the enormous total of 57,430 deaths during the year under report. Taking into account the large increase in the number of vaccinations which has been recorded during these years of growing small-pox prevalence,

suspicion is naturally thrown, as the Sanitary Commissioner observes, on the accuracy of the vaccination returns. "The present arrangement," he says, "by which vaccination in outlying tracts is "practically left to the unchecked supervision of the subordinate inspecting staff, is somewhat risky "and defective." Examples of wholesale falsification of vaccination returns, due to slackness of supervision, are on record in other provinces. It would not be surprising if similar results followed like causes in Bengal. Occasional falsification of vaccination registers cannot, perhaps, be entirely prevented in districts employing a large number of vaccinators scattered over a wide area; but with the exercise of ordinary vigilance, systematic falsification could not long continue undetected. In paragraph 5 of the Vaccination Report for 1902-3, it is estimated that in the province, as a whole, of the total number of children under one year of age available for vaccination, 360·51 out of every thousand were successfully vaccinated. The remaining 639·99 unprotected out of every thousand would obviously supply abundance of susceptible material for the destructive effects of small-pox. In the same paragraph it is shown that, out of every thousand infants in municipalities, taken separately, 723·15 are protected against small-pox by vaccination; in other words, the proportion was almost double that for the province as a whole. Referring to the table in paragraph 16 of the Sanitary Report, it will be seen that, whilst the death-rate from small-pox in rural areas was ·79, it was in urban areas only ·37, or somewhat less than half. The comparison is instructive, in that it shows the small-pox mortality to vary in close accordance with the greater or less proportion of infants vaccinated. In this province, vaccination is still carried on chiefly with humanized vaccine lymph. Of a total of 2,781,972 operations, close upon two millions were performed by the arm-to-arm method; and the percentage of success obtained by this method was slightly greater than that resulting from the use of calf lymph, and much greater than that resulting from the use of lanolinized lymph. The exact figures give the percentage of success in arm-to-arm vaccination to have been 98·38; when calf lymph was used, 98·13; and when lanoline lymph was used, 96·75. In the Madras Presidency, in which arm-to-arm vaccination has been discontinued, and vaccine lymph mixed with glycerine is largely used, the percentage of success following the latter was only 86·9, according to the returns of the preceding year. So far, calf-to-arm and arm-to-arm vaccination have been found to yield the highest percentage of successful cases in India.

6. If the returns of mortality from *plague* could be relied upon, it would appear that there has been a marked decrease in the number of deaths from this disease during the year under report. Whilst the number of deaths attributed to plague was 78,629 in the preceding year, this fell, in the year under report, to 32,967. But, in the words of the Sanitary Commissioner: "This decrease in the "number of deaths seems to be more apparent than real, and is evidently due to the inclusion under "head 'Fever' of numbers of deaths from the septicæmic form of plague which largely prevailed in "Bihar, and which it is very difficult to differentiate from the ordinary malarial fever." Of the three methods adopted for combating plague, disinfection, inoculation, and evacuation of infected houses, the first has failed to secure the confidence of the people, and is generally disliked by them; the second is opposed to their feelings, and has been so little practised as to have had no perceptible influence on the progress of the disease; whilst the last, evacuation of houses, has never failed, where properly carried out, to be followed by an immediate decrease in its prevalence, or by its extinction. The people are at length learning for themselves the lesson which the experience of the Himalayan villagers might have taught them sooner, that in the temporary evacuation of their towns and villages they have at their command an effectual, and, as yet, the only known effectual means of ridding themselves of plague. It is gratifying to learn that evacuation is now carried out "spontaneously and generally fairly thoroughly by the people themselves without outside "interference, which seems to render them suspicious, and hampers their movements. The benefit of "such a timely exodus is most marked, the disease dying out shortly."

7. *Fever* had, as usual, credit for having caused by far the larger proportion of the year's mortality. Under this head were recorded 69 per cent. of the total number of deaths from all causes. But it is acknowleged everywhere in India that no inconsiderable number of deaths attributed to fever are due to other causes. It has been already noted that many deaths due to plague have been registered under the head of fevers. The same might be said of many deaths really due to dysentery, diarrhœa, and respiratory diseases. In a town like Calcutta, with a large staff of trained medical practitioners, and with a comparatively educated population, it will be seen that a death-rate from fever of only 6·59 is recorded against a rate for the province, as a whole, of 23·13. On the other hand, it will be seen that the rate of mortality attributed to "other causes" in Calcutta is 10·53, or almost double that for the province as a whole. So with plague, diarrhœa, cholera, and dysentery: the recorded proportion of deaths attributed to them in Calcutta is, in the case of each, higher than the provincial rate. In other words, the more correct differentiation of the causes of death in Calcutta seems to indicate that, in the rest of the province, a large proportion of the deaths due to other diseases is credited to fever.

8. Estimated by the amount expended upon them, the *sanitary works* carried out in the province during the year would not appear to have been very extensive. On *drainage*, the combined expenditure of all the municipalities was less than two lakhs of rupees; and on *water-supply* less than two and a half lakhs. Quoting from the Government Resolution on the Sanitary Commissioner's Report:—"The Sanitary Board had under consideration during the year a number of schemes for the "improvement of the water-supply, the drainage and the conservancy of various localities, but the work "actually carried out was not of importance." The two chief sanitary wants of the province are well known to be an efficient system of drainage, and the provision of pure drinking water supplies. Without these, little permanent impression is likely to be made on the enormous annual bills of mortality from fever, cholera, and bowel complaints. But judging from the progress made in the past, and taking into account the physical difficulties of the country, its extent, and its 74 millions of inhabitants, mostly poor, the execution of these undertakings is likely to be a work of time, and of a long time.

21st July, 1904.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the United Provinces of Agra and Oudh for the year 1902.

The meteorological conditions of the year did not show any very marked deviations from normal. The rains broke in the first week of July and continued to fall during the following two months of August and September with more or less of regularity. They were in defect in most parts of the province during October; and, except for the fall on the 1st of November, the rest of the year was rainless. Judged by the birth and death rates recorded, the public health was good. Excepting plague, none of the other chief diseases prevailed during the year with unusual severity.

2. The *birth-rate*, which, under pressure of famine, had fallen in 1897 to 31·10, has again risen and at length reached, under the influence of more prosperous conditions, 45·84 during the year under review. It exceeded the death-rate by no less than 13·30 per thousand of population. The proportion of male to female births was 107·25 of the former to every 100 of the latter, and may be accepted as approximately the normal proportion for the province.

3. The *death-rate* of 32·54 was higher than in the previous year, when it was 30·30; and was nearly the same as the quinquennial mean of 32·48. The increase, it will be observed, accompanied the increase in the birth-rate from 41·35 in the previous year to 45·84 in the year under report. It is evident that, whilst infants die at the rate of 243·6 per thousand as compared with a death-rate at all ages of only 32·54, the general provincial death-rate will rise with the rise in the proportion of infants in the population. The high and increasing infantile mortality in these provinces has attracted the attention of the Lieutenant-Governor, who expresses a wish that the Sanitary Commissioner will give the subject his future attention. The following quotation sufficiently indicates that Colonel Thompson clearly realises one, and probably the chief, cause of the high infant mortality recorded in the United Provinces, and, for that matter, in other Indian Provinces: "Excluding the famine period, the high mortality of late years has coincided with high birth-rates. "The infantile death-rate in a European population is usually considered to form a delicate index to "the sanitary conditions under which a community is living, but in a country in which children are "hurried into the world with very little consideration as to how they are to be maintained, it loses "a good deal of such significance." In plain terms, Indian parents produce more children than they have the means of rearing, and hence one of the chief causes of the lamentably high death-rate recorded amongst infants. In several municipal towns the infantile death-rate exceeded 400 per thousand births.

3. As usual, the Report contains a return of deaths the causes of which have been verified by medical officers, medical subordinates, and medical practitioners. Of 10,018 deaths, the causes of which were thus verified, nearly equal numbers were due to *malarial fevers*, to *diarrhœa and dysentery*, and to *respiratory diseases*. Under the head of the first of these there were registered 1,587, of the second 1,565, and of the third 1,586. Comparing these figures with those recorded in the general provincial returns, which are prepared mostly from the reports of the village watchmen, it will be seen that in the latter, instead of each of these three causes contributing nearly an equal number of deaths, fever is credited with a death-rate of 24·51 per thousand of population, dysentery and diarrhœa, together, with ·58; and respiratory diseases, now for the first time separately registered, with only ·33. There is little that is new in this comparison; but its repetition from time to time may be useful in keeping attention fixed on the need for improving the registration of deaths according to their causes. The results of the testing of vital statistics by local authorities and by the vaccination staff, show that, as regards their numbers, deaths are recorded with remarkable accuracy. The omissions detected by the former of these inspecting agencies amounted to 1·7 per cent., and by the latter to only ·29. Considerably over a quarter of a million entries were tested by the local authorities, and somewhat less than a quarter of a million by the vaccination staff.

4. Of the *chief diseases*, none prevailed with unusual severity, excepting *plague*. *Cholera* had attributed to it a death-rate of only ·53 per thousand of population, small-pox of ·10, and fever of 24·51. The mortality from *dysentery* and *diarrhœa* was practically the same as in the preceding year. The mortality attributed to "all other causes" increased from 4·59 to 5·16. "It may be "conjectured that a certain number of cases of plague were still entered under the head of 'all other "'causes.'" Deaths from plague have now, for the first time in these provinces, been recorded in a separate column. The existence of the disease was notified in 34 out of the 48 districts of the province; but in 14 of these the number of cases was very small, and in several was confined to a case in each. The disease has, however, shown an alarming increase within the year. Whilst only 9,778 deaths were attributed to it in 1901, this number has increased during the year under review to 40,223. Females died from it in considerably greater numbers than males. This difference of liability to death from plague, the Sanitary Commissioner thinks "may very possibly be due to the "facts that Native females spend more time inside their houses and court-yards than do men, and, "moreover, do not so habitually wear shoes."

5. Under the head of *Sanitary Works*, a brief statement is given of the amount of water consumed per head by the inhabitants of the eight municipalities provided with water-works. During the year, the quality of the water supplied to these municipalities was, almost without exception, of a high standard of purity. "Many sanitary improvements in various directions have "been effected in municipalities and smaller centres of population during the past year. The "prevalence of plague has drawn increased attention to the necessity for such measures. The "sanitary feature of the year, doubtless, is the great advance made towards efficiently draining "the site and removing the sullage water from the inhabited area in the larger centres of "population."

21st July, 1904.

No. 4.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Punjab for 1902.

Neither in its meteorological features, nor in its prevailing prices of food and rates of wages, was the year unfavourable to the public health. The first two months of the twelve were exceptionally dry. The monsoon set in on the 20th of June and withdrew from Upper India about the 22nd of September. The rainfall during this period was in general defect and, as a consequence, the temperature was high. The last two months of the year were bright and dry, with a comparatively high temperature until the middle of December. The normal rates of food, with which the previous year of abundance closed, were maintained throughout 1902. There was no material variation in wages, except in Delhi, where the great demand for skilled labour during the Durbar caused them to rise, and in the districts of Jhang and Muzaffargarh, where they were lower than in the previous year. Under such conditions a low death-rate might have been expected; and this would doubtless have been recorded, but for a remarkable and fatal extension of the plague epidemic, which, of itself, was the cause of no fewer than 171,302 deaths, equal to about one-fifth of the total mortality from all causes in the province.

2. The *birth-rate* of 43·8 per thousand of population exceeded that of the previous year by 8·4; and was exceeded only by the rates recorded in the United Provinces of Agra and Oudh, and in the Central Provinces. As a striking proof of the accuracy to which the registration of births and deaths has at length attained in the Punjab, the Sanitary Commissioner refers to the last Census Report, from which, he says, it will be seen that there was a difference of only 22,399 between the population of the Punjab according to the census of 1901 and the vital statistical estimate, a figure which, in the opinion of the Census Superintendent, is "really wonderfully small in a population of "over twenty million souls." Notwithstanding the high birth-rate for the year under report, it was exceeded by the death-rate. An examination of the returns shows that this result was due to the enormous mortality in the districts which suffered most from plague. In Ludhiána the mortality exceeded the births at the rate of 67·2 per thousand, in Umballa the rate of excess was 29·2 per thousand, and in Jullundur and Siálkot 14·7 and 12·3 per thousand. This loss of population was made good by the very substantial increase of births over deaths in the Ráwalpindi and Mooltan Divisions.

3. The *death-rate* of 41·1, recorded in the Punjab during the year, was higher than that recorded in any other Indian Province. The increase of 8 per thousand of population over the death-rate of the preceding year was due almost entirely to plague. March and April, ordinarily the healthiest months of the year, were months of high plague mortality and returned the highest death-rates of the twelve. The death-rate amongst infants, calculated on the number living, was 316·44 per thousand for male children, and 320·76 for female children; but calculated on the number of births registered during the year under report, it was only 233·43 and 241·84 for male and female children, respectively.

4. Of the *chief diseases*, *cholera* was, again, for the second successive year, in abeyance, only 371 deaths from it having been registered, following 180 in the preceding year. A local outbreak occurred in a small village in the Kangra Valley and was the cause of 65 seizures and 38 deaths. The history of the outbreak is given in some detail in paragraph 23 of the Sanitary Report. "The Military "Assistant Surgeon, in charge of the Palampur Dispensary, who inquired into the particulars of the "outbreak at the time of its occurrence, found that the origin of the disease was due to the "contamination of the drinking water of one of the village tanks by the washing of the soiled linen of "a sepoy who had returned to the village on the 2nd December from Burma, suffering from diarrhœa "on his way up." The Civil Surgeon of the Kangra District repeats the Assistant Surgeon's statement that the infection was brought to the village by a sepoy returning from Burma, whose clothes were washed by his wife in the tank from which one half of the village procure their drinking water. The half of the village using water from the polluted tank suffered from cholera; whilst the other half supplied from another source escaped. The evidence in support of the pollution of the drinking water and of the diffusion of cholera in consequence of this pollution, has the appearance, at first sight, of being complete. But there are one or two links in the chain which are missing. In the first place, it is not stated that the sepoy was suffering, or had been suffering, from cholera. His complaint is described as "diarrhœa"; and if it was diarrhœa, and nothing else, it is not clear why it should have been the cause of an outbreak of cholera. The circumstance of Burma having been the country from which the man came, would not strengthen the case, unless it were shown that cholera was prevalent in the particular part of that province in which he had been. Even then, had he become infected with cholera in Burma, it might be expected that he would have developed the disease and either have died or recovered from it long before he could reach the Kangra Valley. Moreover, although it is stated that the sepoy reached the village on the 2nd December, the date on which the first case of cholera resulting from drinking the water polluted by his clothes having been washed in it, is not given. The report concludes:—"The inhabitants ceased to use the infected water, "and the tank was disinfected by the permanganate of potassium—the cases ceased immediately." If, as this account seems to imply, the tank was disinfected by permanganate of potassium after the villagers had discontinued using water from it, the influence which such disinfection could have exercised in cutting short the epidemic is not apparent. This isolated outbreak was one which would seem to have afforded facilities for tracing the disease to its source; but the evidence adduced in support of the conclusion that the sepoy from Burma introduced the infection is incomplete.

5. *Small-pox* was nearly twice as fatal as in the preceding year, accounting for 11,629 deaths, or a ratio of 0·58 per thousand of population, as compared with 0·31 in the previous year, and with a mean ratio of 0·36 for the preceding five years. The number of deaths due to it amongst infants under one

year of age was 26 per cent. of the total small-pox deaths in the Province. In towns the disease was nearly twice as fatal as in rural areas. A list of towns is given, with small-pox death-rates rising from 5·12 to 11·83 per thousand of population. In none of these towns was vaccination compulsory. On the other hand, of the 22 towns in which vaccination is compulsory, in not one did the small-pox death-rate exceed 1·6 per thousand; and in four of them not a single death from the disease was recorded. The number of vaccine operations recorded during 1902–3 fell but little short of the number recorded during the previous year, in spite of the work of the department having been much impeded in some parts of the Province by the prevalence of plague. The Sanitary Commissioner, in his Notes on Vaccination, puts on record that the Deputy Sanitary Commissioner "was employed "under the orders of Government on special duty—testing plague prophylactic bacteriologically—from "9th December, 1902, to 7th March, 1903, that is, during the most important part of the cold weather "vaccination season, and was accordingly unable to give much attention to the superintendence of "vaccination work." It has repeatedly been demonstrated that, without unremitting vigilance on the part of the European Staff of the Department, the system of vaccination practised in India cannot be satisfactorily carried out. Only too many instances are on record of the disastrous effects resulting from insufficient supervision: sometimes the returns are falsified; frequently operations which have failed are returned as having been successful, and the faith of the people in the protective power of vaccination is, in consequence, shaken and not readily restored.

6. But for the fatal epidemic of *plague*, which was accountable for a large proportion of the total mortality, the history of the public health of the Province during the year under report would have been comparatively uneventful. The ravages of this disease, in its most destructive form, were fortunately confined to a few districts. In seven of these, 90 per cent. of the plague mortality occurred. The district of Ludhiana was the greatest sufferer, losing, as it did, from plague alone, 71 out of every thousand of its population. The epidemic followed its usual course, "increasing rapidly "in the winter months, reaching its climax in the spring, and declining suddenly with the commence-"ment of the hot weather, and disappearing almost entirely in the months of July, August, and "September." It is stated by the Civil Surgeon of Ludhiana "that rats, as a rule, were found dying in "every village before the commencement of outbreaks of the disease among the inhabitants, and that "those villagers who went out at the discovery of rats dying and did not visit their houses, mostly "escaped." This is but a repetition of the history of local outbreaks in Himalayan villages, many years before the commencement of the present epidemic in Bombay City, towards the end of 1896. Immediate evacuation of infected dwelling-houses, the remedy hitherto found to be most effectual in extinguishing plague outbreaks in the hills, is shewn by the experience of the past seven years to be the most efficient means yet discovered for extinguishing them in the plains.

7. As regards *fever* prevalence, the year may be described as having been fairly normal. The death-rate attributed to this cause was 23·54 per thousand of population, or nearly the same as the mean ratio for the previous quinquennium.

8. The death-rate recorded under the head of *dysentery and diarrhœa* is probably far from representing the actual rate due to these causes. In our *Memorandum* on the Sanitary Report for the United Provinces, reasons based on the returns of deaths, according to their causes, furnished by medical men, have been given for the belief that, whilst the number of deaths attributed in the returns to fever is exaggerated, the number attributed to dysentery, diarrhœa and to respiratory diseases is greatly understated.

9. The report submitted by the Sanitary Board and the Sanitary Engineer to Government, testify to considerable activity in the endeavour to improve the water-supply and drainage of towns and villages. The need for such improvements is fully recognized; but their execution is retarded by the lack of a sufficiency of funds.

21st July, 1904.

No. 5.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Administration of the North-West Frontier Province for the year 1902.

The year was a very dry one. The rainfall of 3·9 inches was the lowest recorded in Peshawar for the last 26 years. As a consequence of this exceptional dryness, it might have been expected that the year would have been more than usually exempt from fever. Such was not, however, the case, the fever death-rate having been 18·92 per thousand of population, or 4·30 higher than the rate for 1901, and 2·19 higher than the mean ratio for the previous five years. Except in one of the five districts of the Province, the price of food grains, and the rates of wages remained nearly the same as in the preceding year, and the people did not appear to have suffered from scarcity of food. In the district of Bannu the rainfall was scanty and food prices were high, but there was very little consequent distress, and the Civil Surgeon did not notice any ill-effects on the health of the inhabitants to follow.

2. The *birth-rate* rose to 33·6 per thousand of population, showing an increase of 3·3 over that of the preceding year and of 2·9 over the mean rate of the preceding five years. In this increase it is probable that improved registration of vital statistics had a share. As an indication of the improvement being effected in registration, the tendency of the proportion of male to female births to approximate, may be noted. In the previous year, 123·2 births of males were registered for every

100 births of females; in the year under report the proportion was 121·9 of the former to 100 of the latter. The disproportion is still abnormal, but may be expected to diminish as registration becomes more accurate.

3. The *death-rate* increased from 19·7 in the previous year to 24·4 in the year under report, and was higher than the mean for the previous five years. The mortality record would not, therefore, support the Administrative Medical Officer's opinion that the year "may be considered a healthy "one" It is true that there was an entire absence of cholera, and that only a few imported cases of plague were reported; but, on the other hand, fever prevailed in epidemic form in some districts, accounting, by itself alone, for a death-rate of 26·96 per thousand of population in the district of Kohat. A comparison of its mortality records with those for other provinces would lead to the conclusion that, as the Administrative Medical Officer remarks, the North-West Frontier Province is the healthiest, next to Madras, in India. The comparison might rather suggest, however, that registration of vital statistics is more defective in this than in any other of the Indian provinces, with the exception of Madras. The testing of the entries in the birth and death registers during the year by the inspectors of vaccination shows that a large proportion of the births and deaths remained unrecorded. Of 17,459 births verified, no fewer than 2,358 were discovered to have escaped registration; and of 13,354 deaths no fewer than 1,451. The testing of the registers by vaccinators would, by comparison with the foregoing figures, appear to be wanting in thoroughness. Of 25,913 births, said to have been verified by them, only 566 were found to have been omitted; and of 17,379 deaths only 219. The contrast between the results obtained by these two inspecting agencies seems to suggest excess of zeal on the part of one of them, or want of it on the part of the other. As a consequence of the persistent scrutiny to which the registers of births and deaths are subjected in the province, "a distinct improvement" in registration is said to be perceptible.

4. *Chief diseases.*—From *cholera* the province was entirely free; and although four deaths were caused by *plague*, none of the four occurred amongst the indigenous population; the cases were all of them imported from the Punjab. *Small-pox* was, however, more fatal than in the previous year. and to this cause were ascribed 1,081 deaths, equal to a ratio of 0·54 per thousand of population, Vaccination made satisfactory progress, the number of operations exceeding that of the previous year by 19,300, or 27·19 per cent. This increase was accomplished without any addition to the vaccination staff, which remained of the same strength as in the preceding year. A satisfactory feature of the season's work is the high proportion of infants vaccinated. These constituted no fewer than 43,951 of the total number of 77,030 successful primary vaccinations. By far the larger proportion of deaths from all causes was registered under the head of *fever*. To this cause was ascribed a death-rate, per thousand of population, of 18·92, the total from all causes having been 24·43 for the province. In the district of Kohat fever was especially fatal, accounting, according to the returns, for no less than 26·96 deaths per thousand of population.

5. Although no *sanitary works* of magnitude were executed during the year, important improvements in the water supply and drainage of towns were carried out. In the Dera Ismail Khan district, "all the water tanks are reported to have been cleaned, as well as all the wells in the town "from which drinking-water was obtained." In no direction could the limited amount of funds available for sanitary purposes have been expended to greater advantage. It is disappointing to read that "no rewards were paid or *khillats* given during the year to village communities for special "interest taken in sanitary improvement." The Administrative Medical Officer adds, that the issue of village sanitary note-books does not appear to have been attended with any success.

21st July, 1904.

No. 6.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1902.

The year was a healthy one. The rainfall, both in Lower and in Upper Burma, was considerably less than the amount recorded for the previous year, and also than the mean for the five-year period 1896–1900.

2. The registration of vital statistics continues still to be limited almost entirely to Lower Burma, with its population of somewhat over five and a half millions. In Upper Burma, births and deaths are recorded only in thirteen towns, with an aggregate population of 300,969. In Annual Form No. II. of the Appendix to the Sanitary Report, the population numbers for the districts of Upper Burma are not shown.

3. The *birth-rate* recorded in Lower Burma for the year under review shows a decrease of ·5 per thousand of population, as compared with that for the previous year. There can be no doubt that the recorded birth-rate of 31·57 is much below the real birth-rate. Whilst the census figures of 1901 showed that during the preceding ten years the population of Burma had increased by 24 per cent., the increase calculated by adding the excess of births over deaths for the same period was only 14 per cent. Leaving out of count the additions to the population resulting from immigration

during this period, these figures would indicate that a very large proportion of the births remained unregistered. In paragraph 3 of the Report, the Sanitary Commissioner states that, of the 17,111 villages and towns under registration in Lower Burma "the registers of 48·2 per cent. were inspected "during the year under report." What such "inspection" implies is not explained; but it is pretty safe to assume that a house-to-house inspection was not made in 48·2 per cent. of these 17,111 villages with the object of ascertaining if all of the births and deaths which actually occurred in them were recorded in these registers. To carry out such an inspection would imply the expenditure of more time and labour than civil surgeons, vaccinators, and district officials would have at their disposal for such a duty. And yet, to determine whether the entries in the village registers accurately correspond with the births and deaths which have occurred in the villages, only such a house-to-house inspection can be relied upon. Instead of attempting the inspection of so large a proportion of the registers—an inspection which cannot well be thorough—it might be found to be more effectual in improving registration if the accuracy of a smaller number were tested by a careful house-to-house inspection in certain selected towns and villages.

4. The *death-rate* of only 21·16 recorded for the year is, like the birth-rate, abnormally low: and this is doubtless mainly due to defective registration. In the towns of Lower Burma, in which registration is probably better effected than in the country, the death-rate was 29·93 per thousand of population; whilst in rural areas the rate was only 19·97. The rates of deaths amongst children under one year of age per 1,000 living was, for males, 307·47, and for females, 221·89; but calculated on the number of births recorded for the year under report, it was only 217·57 for the former and 173·17 for the latter. With registration still so imperfect no great reliance can be placed on those figures.

5. Under the head of each of the *chief diseases*, except fever, fewer deaths were recorded than in the previous year. Neither Upper nor Lower Burma suffered much from *cholera*; in the former, 1,344 deaths were attributed to this disease, and in the latter only 57.

6. *Small-pox* was credited with only 1,565 deaths or less than half the mean number for the five years 1897–1901. The death-rate per thousand of population from this disease only amounted to ·28. Although the combined returns for Lower and Upper Burma show an increase in the number of persons vaccinated of 17,534 as compared with the number for the preceding year, the whole of this increase took place in Upper Burma. The returns for Lower Burma show a decrease, which the Sanitary Commissioner attributes to the attitude of the people, many of whom prefer inoculation to vaccination. A closer supervision of the work of vaccinators, and the punishment inflicted for falsifying returns are also assigned as contributory causes of the decrease. The class of men who take service in the Vaccination Department in Burma is said to be indifferent. The last of these three causes, the inferior stamp of candidate for employment as a vaccinator, is, perhaps, the most important. Better pay would doubtless attract better men. Whilst the people are still so unfavourably disposed towards vaccination, it is unlikely that vaccinators receive much beyond their pay for their services. The lot of the vaccinator in a country of which the inhabitants are hostile to vaccination is not an enviable one. The percentage of successful cases in primary vaccination was as low as 87·14 as compared with 90·27 in the preceding year. This falling-off is probably due to the closer supervision to which the work of the vaccinators is now subjected. It may also indicate deficient knowledge and skill on the part of the operators. "The quality of the lymph was "on the whole satisfactory." For its supply 386 calves were inoculated.

7. The death-rate ascribed to *fever* in Lower Burma was 8·86 per thousand of population as compared with a mean of 10·93 for the previous five years. If these figures can be relied on, the mortality from fever in Burma is less than in any other province of the Indian Empire, except Madras. But both in Burma and Madras, the former of which returns a death-rate from all causes of 21·6 and the latter of 20·2, defective registration, rather than greater healthiness, would probably account for the lowness of the death-rate as compared with that recorded in other provinces.

8. Regarding *plague*, quoting from the Government Resolution on the Sanitary Report, "the "stringent measures enforced against the introduction of plague have again been attended with "success." Three imported cases were detected in the port of Rangoon at the medical inspection imposed against all vessels arriving from India.

9. *Sanitary Works* made some progress in the chief towns. The successful sinking of tube wells in Rangoon has made it possible for that city to discontinue the use of water from the Royal Lake, which had repeatedly been condemned as unfit for drinking purposes; whilst the "Hlawga" water-supply scheme, estimated to cost 39 lakhs of rupees, has been more than half completed. In Upper Burma the water-supply and conservancy schemes make but little progress. According to the Government Resolution:—"The water-supply scheme is advocated mainly on behalf of the "troops and other inhabitants of cantonments, and progress cannot be made owing to delay in "working out the cantonment part of the project." The scheme for providing Moulmein with a water-supply is already well advanced toward completion; whilst that for Akyab has been submitted to the Sanitary Board for approval. The water-supply of Prome is being extended and improved; whilst the surface drainage of the town is said to be making steady progress. Judging from the small sum of less than two lakhs of rupees expended on district sanitation, it may be concluded that only sanitary works of a minor description were undertaken during the year.

21st July, 1904.

No. 7.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Central Provinces for 1902.

This Report has already been dealt with so thoroughly in the Government review attached to it that further comment seems scarcely to be called for. It is true that the section on meteorology is, in accordance with the Government of India, omitted from provincial Sanitary Reports; but nevertheless, without going into details, it would be useful to have a paragraph given to an account of the general climatic features of the year and of the harvests, together with some estimate of the influence which these may appear to have had on the public health. Nothing is said of the character of the season, beyond the remark incidentally made in connection with the subject of fever prevalence, that "it was a dry year."

2. Judged by its record of births and deaths, the year was a very healthy one. The birth-rate was unusually high, having risen to a ratio of 48·29 per thousand of population, as compared with 28·83 in the previous year, and with a mean of 45·16 for the decennium. It might have been expected that so large an increase in the birth-rate would have been accompanied by a corresponding increase in the death-rate; but the latter only rose from a ratio of 23·46, in the previous year, to a ratio of 25·82 in the year under report. The fall in the infantile death-rate from 246·41 in the previous year to 228·10 in the case of male children, and from 224·63 to 206 in the case of female children, may be accepted as reliable evidence of the greater healthiness of the year under report.

3. Considerable space is devoted to an account of the measures taken to bring to light defects in the registration of vital statistics. Some misapprehension seems still to exist on this question, although an endeavour was made in our *memorandum* on the Sanitary Report of the Central Provinces for 1900 to make it clear that a comparison of the entries of births and deaths in the village watchmen's handbooks with those made in the registers kept at the police stations would fail to supply evidence of the omission to report births and deaths. The figures given in paragraph 25 of the Report show that the numbers of births reported by the *kotwars*, or village watchmen, differ but slightly from the numbers registered by the Police, the former being 63,398 and the latter 63,361; in other words that the clerks at the Police stations transcribed with tolerable accuracy into their registers the entries of births and deaths found in the *kotwars*' handbooks. The *kotwars*' books and the Police registers might be in exact agreement, and yet hundreds of births and deaths may have escaped, and probably did escape, record by the *kotwars*. In the table given in paragraph 26 it will be seen that Police officers in checking, doubtless by house-to-house inquiry, 150,719 entries in the *kotwars*' books, discovered 1,735 omissions; and that Civil Surgeons in testing 21,031 entries similarly discovered 344 omissions. These figures are in marked contrast with those shown in the preceding paragraph, where the number of births reported by the *kotwars*, registered by the Police, and verified by Native Superintendents are in close agreement, the *kotwars* recording 63,399, the Police 63,361, and the Native Superintendents 63,324. Of these three sets of numbers it is safe to assume that the first set is more likely to be correct than the last two: *kotwars* frequently omit to report the occurrence of births and deaths; but it is believed they rarely, if ever, venture to enter births and deaths which have not occurred.

4. Of the *chief diseases*, *cholera* was practically absent from the Province, only 28 deaths having been ascribed to it during the year. *Small-pox*, although less fatal than in the previous year, still accounted for 4,394 deaths. Vaccination appears, from the returns, to have made satisfactory progress, primary operations having increased by 69,869 as compared with the previous year's numbers. In re-vaccination there was, on the other hand, a decrease of 9,019 operations. One of the most favourable features of the year's work was the high proportion of children under one year of age who were successfully vaccinated. In the Province, as a whole, 79·37 of the infant population available were successfully vaccinated; in one district the ratio was 92·70. The percentage of successful cases recorded in primary vaccination was 97·13, and in re-vaccination 85·14. The latter figures are high; and the Administrative Medical Officer observes that "it is difficult to understand "the very successful results of re-vaccination recorded in some districts." Fresh calf-lymph and humanized vaccine lymph yielded almost the same percentage of successful cases, and both gave better results than glycerinated calf-lymph. The number of calves, 10,334, required for the supply of lymph seems very large. According to the table given in paragraph 15 of the Vaccination Report, 337,823 operations were performed with calf-lymph. Each of the calves successfully inoculated would, consequently, have afforded lymph for the vaccination of rather less than 35 persons.

5. The deaths attributed to *plague* numbered 1,061; but the Administrative Medical Officer gives good reasons for the belief that this number is far short of representing all the deaths actually caused by this disease. The difficulties with which the authorities have still to contend in their endeavours to prevent the ingress of plague into a town, or to stamp it out when it has secured a footing, are well exemplified in the case of Burhanpur:—"The attitude of the people was from the " first unsatisfactory. They would not have it that there was plague in the town; they concealed the " cases; they resented everything that was doneto check the spread of the disease, and only asked to " be let alone. The result was a virulent and widespread epidemic, which has only quite recently " come to an end after inflicting enormous damage on the town."

6. Following upon recent discoveries regarding the causation of malarial fevers, the question of the prevention of these diseases has received special attention in the Central Provinces. Systematic operations for the destruction of malaria-carrying mosquitoes have been recommended by the Administrative Medical Officer, and approved of by the Government, in certain selected municipalities. In so far as these operations include the filling up of hollows in which water lodges, and the

drainage of town sites, only benefit to the public health can result; but, to quote from the Report of the anti-malarial operations at Mian-Mir 1901-03 :—"The destruction of *anopheles* within an area by "attacking their breeding-places is extremely difficult. Although large numbers of pools were filled "up and drained, and millions of larvæ destroyed by oil, adult *anopheles* were still abundant The "mere obliteration of local breeding-places is useless. In Mian-Mir almost complete absence of "breeding was ensured to a distance of over half a mile, but adults appeared in large and increasing "numbers in the area." The Report concludes: "Moreover, it appears to us that gradual but "permanent improvement in the health of stations by well-directed sanitary reforms, whenever these "can be carried out, will in the end yield the best return." A writer in the British Medical Journal says it is almost the universal opinion in India that "destruction of *anopheles* as a method of malarial "prophylaxis is a hopeless measure in that county, even in unusually favourable conditions, while in cases such as Lower Bengal it would be sheer folly and waste of money to attempt it." A measure, regarding the beneficial effects of which in the campaign against malarial fevers there can be no room for doubt, is the distribution throughout the Province of quinine. Every facility is provided by the Administration for the purchase of the drug; and the growing demand for it affords evidence of the appreciation by the people of its usefulness.

7. The paucity of important *sanitary works* executed during the year was due to lack of funds and not to the absence of urgent need for such works. "Under the head of rural sanitation most of "the work consisted of clearing village sites and maintaining village sanitation in the ordinary way." Sanitary work of this nature is probably as much as the resources of the villages will admit of being carried out; it is none the less useful because of a simple and unpretending character.

21st July, 1904.

No. 8.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner for Assam for 1902.

The Sanitary Commissioner gives a concise account of the meteorological conditions of the year under report. The province consists mainly of two distinct parts, the Brahmaputra and the Surma Valleys, of each of which the climatic features differ widely. In the Brahmaputra Valley, the rainfall is usually 20 or 30 inches less than in the Surma Valley. The temperature and other climatic conditions of the latter are practically the same as those of Lower Bengal. The upper and lower parts of the Brahmaputra Valley record nearly the same rainfall, but the temperature of the former is lower than that of the latter, whilst both are cooler than the Surma Valley. During the year under report it is stated that, in the Surma Valley, the rainfall was abundant, although not excessive; and that no unusual climatic phenomenon was observed. Likewise, in the Brahmaputra Valley, the year presented no abnormalities and corresponded closely with the average of the three preceding years. So far as the Sanitary Commissioner can judge, the variations in the prices of the food grains in Assam have little, if anything, to do with the birth-rate. In this view, the Government concurs. "Mr. Bolton accepts the opinion that the prices of food grains have no influence on the birth and "death rates in Assam." The people are described as being well-off; food is plentiful everywhere, and life taken so easily that only a minimum of work is done anywhere. Famines are unknown. Into such a country it might be expected that immigrants would pour voluntarily from the congested districts of Bengal and the United Provinces, where the conditions of life are, at the best of times, the reverse of those described as prevailing in Assam.

2. The health of the province during the year under report is said to have been "extremely "good." The *birth-rate* recorded was 34·21 and the *death-rate* 29·01 per thousand of population. There can be no doubt that both are much below the actual rates, owing to the defective state of registration still prevailing in most of the districts of the province. Accepting them as recorded, the birth-rate exceeded the death-rate by 5·20 per thousand. The weakest part of the system of registration of vital statistics in Assam is the employment of unpaid *gaonburas*, or village headmen, in five of the eight districts of which the province consists, for the record of births and deaths. In the remaining three districts registration is effected by paid village watchmen and is comparatively well done. With a view to giving the unpaid village headman an interest in the better performance of his registration duties, "the Administration has submitted a proposal to make a revenue-free grant "of $3\frac{3}{4}$ acres of land to each *gaonbura*, at an estimated cost of Rs. 40,000 per annum." Meantime, energetic measures are employed to obtain from both classes of agencies, paid and unpaid, more accurate returns. As a result of the inspection of registration during the year by members of the Police and Vaccination Departments, no less than 31·5 per cent. of all the births and 29 per cent. of all the deaths in the province were subjected to inquiry. Of the former, 5·8 per cent. were found to be unrecorded, and 5·3 per cent. of the latter.

3. But for its severe epidemic prevalence in a single district, *cholera* was in comparative abeyance throughout the province during the year. Of a total of 12,658 deaths from this disease, no fewer than 8,804 occurred in Sylhet alone, a district in which cholera is endemic. Although, as a result of this outbreak, the mortality due to cholera exceeded that of the preceding year, it was still much less than the average for the 16 years 1884–99. The death-rate from cholera among tea-garden coolies, whilst in transit from Goalundo to the port nearest to the place of their employment, was 0·9; and was only once lower during the fifteen years for which records are available in the Sanitary

Commissioner's office. This fall in the rate of mortality amongst these coolies shows, the Sanitary Commissioner thinks, that greater precautions are taken on the steamers, and greater care taken not to ship infected coolies. "The garden rates were everywhere higher than the general ones, except in the Sylhet district, where the mortality was four times as high as in last year." This higher death-rate from cholera in tea gardens, if actual and not merely apparent, is remarkable in view of the better sanitary conditions under which the tea-garden coolies are compelled to live; and suggests that it may be due to the greater accuracy with which deaths from cholera, as from all other causes, would presumably be recorded on tea gardens than amongst the general population.

4. *Small-pox* prevailed in severe epidemic form in the two districts of the Surma Valley. Of the total number of 6,673 deaths recorded from this disease, all except 304 took place in these two districts. The Sanitary Commissioner attributes the epidemic to the dissemination of small-pox contagion by inoculators, and thinks that the operation of inoculation could, and should, be made illegal, and the Ganaks performing it made punishable by law. The returns of vaccination deal with the entire population of the Province of Assam, numbering 6,126,343; whereas the returns relating to vital statistics do not deal with those portions of the province in which births and deaths are not recorded, such as the hill tracts and the State of Manipur, and relate only to a population of 5,275,706. If the state of protection against small-pox conferred on the population by vaccination might be estimated by the ratio per thousand vaccinated, deaths from small-pox in Assam should be few in number. According to Statement I. in the Appendix to the Report on Vaccination for 1902–03, the ratio of persons successfully vaccinated per thousand of population during the year was 48·18, or much in excess of the provincial birth-rate. But this ratio varies greatly in the different districts; in Cachar it was only 16·72, the lowest recorded; and in this district the small-pox death-rate, 2·71, was the highest. As an indication of the slight influence which vaccination is likely to exercise on the prevalence of small-pox in this district, it may be noted that, whilst the births registered during the 12 months of the calendar year 1902 numbered 14,759, the children under one year of age successfully vaccinated numbered only 1,247 during the 12 months of the vaccination year 1902–03. The quality of the vaccine lymph is said to have been generally excellent throughout the year; and this is confirmed by the high percentage of 97·90 successful cases recorded in primary vaccination. But when, as in the case of the returns for the Khasia and Jaintai Hills, one finds cent. per cent. of 4,241 primary vaccinations recorded as "successful"; and still more remarkable, cent. per cent. of 143 re-vaccinations also recorded as "successful," doubts are apt to arise as to the trustworthiness of the returns.

5. The mortality from *malarial fevers* shows a considerable decrease as compared with that recorded in the preceding year; whilst the number of deaths ascribed to *kálá ázár* is almost the same as in 1901. It might be concluded from the returns that the invasion of Sylhet by this disease was sudden; but the Sanitary Commissioner writes: "I saw many cases myself, both in 1899 and in 1900, which I have no doubt in the world were genuine *kálá ázár*, but it was not until an officer was deputed on special duty to visit each village in turn that the extent of prevalence of this dreaded disease was known."

6. An interesting inquiry is being made into the cause of the greater mortality from *dysentery* and *diarrhœa* amongst tea-garden coolies than amongst the general population of the province; but no definite conclusion on the question has yet been reached. The Civil Surgeon of Lakhimpur finds that, whilst the tea-garden coolies suffer about three times as much as the other classes of the people from bowel complaints, they ail about three times less from fevers; the result being that the combined mortality due to fever and bowel complaints is about the same in the case of both. This would seem to suggest that the difference may be due rather to difference of diagnosis than to greater fatality from bowel complaints among the tea-garden coolies; some of the deaths registered as due to fever among the general provincial population being more correctly attributed to dysentery or diarrhœa in the case of the tea-garden population. It may, however, be noted with regard to the tea-garden coolies, as it has been noted by some medical officers with regard to prisoners in Indian jails, that the change from the scanty dietary on which they probably subsisted at their homes prior to their recruitment to a fuller dietary whilst employed in the tea-garden may have tended to induce derangement of the alimentery tract and diarrhœa or dysentery.

7. According to the Government Resolution on the Report, no *sanitary work* of any magnitude was undertaken during the year; but useful work was done by Local Boards in improving the water supply.

21st July, 1904.

No. 9.

Memorandum by the Army Sanitary Commission on the Rajputana Sanitary, Vaccination, Dispensary, and Jail Report for 1902.

As noted in previous *memoranda*, and is still the case, the only portion of Rajputana which records vital statistics having any claim to accuracy is Ajmer-Merwara with its population of less than half a million. In the greater part of the Province, consisting of Native States with a population of close on ten millions, the returns of births and deaths are so inaccurate as to possess little or no value beyond showing the need for improving them.

2. The year under report was marked by scarcity and famine in Ajmer-Merwara and in some of the Native States. The rainfall was tess than the average and the prices of food were high ; but in spite of these unfavourable conditions the year was a healthy one. Whilst the number of deaths remained nearly the same as in the preceding year, showing a slight decease, the number of births more than doubled. The remarkable increase in the birth-rate from 16·10 per mille of population in the preceding year to 36·08 in the year under report, is stated to have been "the result of recovery from famine conditions and probably also of improved registration." It may be taken as some indication of the improvement in registration that the percentage of male to female births recorded fell from 119·15 in the previous year to 115·25 in the year under report. Some idea of the defective condition of the registration of vital statistics still prevailing in the Native States may be gained from a study of the table in paragraph 8 of the Report. Whilst a birth-rate of 18·38 for the Native States, as a whole, is recorded, one of the largest of them returns a rate of only 11·05 ; another of 4·27 ; and a third of 2·29, per thousand of population. It is the same with the record of deaths. Whilst the general death-rate is stated to be 17·10, several States return ratios of less than 15 ; and one State a ratio of only 2·0. Calculated on the number of children under one year of age living when last census was taken, the infantile death-rate works out to no less than 609·69 per thousand. If, however, the rate is calculated on the births recorded for the year under report, it is found to be only 216·9 per thousand. But for the exceptionally large number of children born during the year under report, the death rate for Ajmer-Merwara would have been lower than recorded ; for it is evident that the addition to a population of less than half a million of 17,207 persons who died at the rate of 216 per thousand, compared with a death-rate of only 32·86 per thousand at all ages, must have a marked effect in raising the general death-rate.

3. Of the chief diseases, *cholera* accounted for only 32 deaths in Ajmer-Merwara ; giving a ratio of 0·07 per mille of population, as compared with a mean of 2·06 for the previous five years. From the Native States 1,519 deaths were reported from this disease ; but no great reliance can be placed on these figures. *Small-pox* was almost entirely absent from the Ajmer-Merwara Division, having been credited with only three deaths during the year. Vaccination continued, as in former years, to yield extraordinarily high percentages of successful cases. In primary vaccination, according to the return on page 28 of the Appendix of the Report, a percentage of 99·18 was attained in Ajmer-Merwara, and of 98·91 in the Native States. In the Native State of Kishnagarh, of 1,786 primary vaccinations all are returned as having been successful. In paragraph 38 of his Report the Residency Surgeon and Chief Medical Officer states that he "gave considerable attention to the high percentage of successful vaccinations." In certain other provinces it has been found that some vaccinators adopt a method of preparing their registers which enables them to return all their operations as "successful." At the time of vaccinating they enter the names and other particulars of each case on a slip of paper, and not in the Departmental printed or lithographed register. When they return, after a week, to ascertain the results of their operations, they strike out from this slip of paper the unsuccessful cases before transcribing the names into the permanent official register. In this way they are able to show all their operations to have been successful ; whilst the most careful examination by the inspecting officer fails to detect any mistake in the registers. It may possibly be from their adoption of this, or some other ingenious method in the preparation of their returns that vaccinators in Rajputana are able to show the striking results published in the annual reports,

4. Of the comparatively few cases of plague reported in Ajmer-Merwara, nearly all were imported, only two deaths occurring amongst the indigenous population. In the Native States of the province 1,070 cases with 869 deaths were recorded.

5. Over-crowding existed in the Ajmer jail ; but although the daily average number of sick increased from 7·58 in the previous year to 12·38 in the year under report, the death-rate fell from 36·18 to 29·60 per mille of the jail population. There was a satisfactory decrease in the mortality from dysentery and diarrhœa, as well as from lung and respiratory diseases, ordinarily the most fatal diseases of Indian jails. In the jails of some of the Native States the sickness and mortality continue to be excessive. The Banswara jail maintains its evil reputation ; its death-rate rose from 129·35 in the previous year to 272·28 in the year under report. "It is proposed," the Chief Medical Officer writes, "to construct a new jail on a healthy site." The Dungarpur jail, with its death-rate of 217·47 per thousand of average strength, would appear to be little behind that of Banswara in point of unhealthiness. Such figures may be left to speak for themselves.

21st July 1904.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1902.

The Report of the Sanitary Board precedes that of the Sanitary Commissioner. The functions of the Board are neither administrative nor executive but advisory only. During the year many sanitary schemes were examined of an estimated cost varying somewhat over seven thousand rupees to upwards of five lakhs each. Some new type designs were also prepared, and such questions as the destruction of rats, latrine accommodation and mortuaries considered.

2. The Sanitary Report begins with a brief but useful account of the season's rainfall, and of the prices of the ordinary food of the people. The rainfall is described as having been favourable. It

measured 53·73 inches as compared with 47·80 in the previous year, and with a decennial average of 44·89. Following the good rainfall, food grains were less expensive. The effect of these conditions on the public health is shown in an increased birth-rate and a diminished death-rate. Emigration at the same time declined, as it is said to do in prosperous years, immigrants exceeding emigrants by 47,505.

3. The *birth-rate* of the Presidency rose to 28·2 per thousand of population, showing an increase over that recorded for the previous year, but still falling short of the mean ratio of the previous five years by 0·7. There can be no doubt that, owing to defective registration, these figures fall far short of the real birth-rate. The birth-rates recorded in the adjoining provinces of Bombay and Bengal for the same year were 34·16 and 40·14 respectively. In contrast with the general rate of 28·2 recorded for the Presidency, "61 towns under municipal rule where compulsory registration of births and deaths is enforced by the employment of special staffs," with an aggregate population of close upon two and a half millions, record a birth-rate for the year of 32·7 per mille. From which it may be inferred that more efficient registration has enabled those towns to show a higher birth-rate than the rural and town circles in which registration is not compulsory. The Sanitary Commissioner has suggested to the Government that in 306 villages, lying in 21 districts, where medical subordinates are employed, the services of these men might be utilized for the purpose of registering deaths according to their causes. In this way, he thinks, "a gradual accumulation of evidence as to correct nomenclature and distribution of diseases" in the Presidency would be secured. The experiment proposed would deal with a population exceeding two millions, and if carefully carried out would undoubtedly furnish a reliable record of the actual number of deaths and of the diseases to which these deaths were due. The suggestion does not, however, commend itself to Government.

4. Owing chiefly to the diminished prevalence of cholera, the *death-rate* of the year under report has fallen to 20·2 from 21·1 in the previous year. The actual rate is undoubtedly much higher than the recorded rate. No fewer than 11 districts return death-rates of less than 20 per thousand of their population; and one of these, Ganjam, records a rate of only 11·9. In the case of deaths, as of births, the ratio recorded in town circles is much higher than that recorded in rural circles. Whilst in the former the rate was 28·2, in the latter it was only 19·3. Registration of vital statistics may be, and doubless is, defective in the towns, but it is obviously more so in the country. The recorded infantile death-rates in urban and rural areas are consistent with this belief. In the former the infantile death-rate recorded was 233·3 per thousand births; in the latter it was only 168. The Sanitary Commissioner thinks there is room to believe that both rates represent facts as found. In this opinion the Government, for reasons which appear to be conclusive, is unable to concur.

5. Of the chief diseases, *cholera* had attributed to it a death-rate of 0·8 per mille of population. The most important fact connected with the history of the disease during the year is the employment of Certificated Sanitary Inspectors for dealing with cholera outbreaks, in place of the vaccinators and others hitherto deputed on this duty. The change cannot fail to be beneficial. Experience has clearly shown that, in preventing or cutting short cholera outbreaks, efficient sanitary arrangements can alone be relied on. Medical treatment of people attacked by the disease may alleviate individual suffering, but can have little, if any, influence on the progress of an epidemic.

6. *Small-pox* was credited with 24,967 deaths, equal to a ratio per thousand of population of 0·7. This was the ratio recorded for the preceding year, and also the mean for the five previous years. With this may be contrasted the mortality from small-pox in the neighbouring presidency of Bombay. In the year under report the ratio of deaths per thousand of population in Bombay was 0·12; whilst the mean for the previous five years was 0·24. The Sanitary Commissioner again urges the need for the reorganization of the Vaccination Department. He says: "I would take the liberty of repeating my trite statement that the *personnel* of the Vaccination Department in this Presidency is badly paid, badly educated, and, by reason of multiple masters, badly disciplined." It appears that the Inspector of Vaccination, who is also Deputy Sanitary Commissioner and Professor of Hygiene and of Practical Bacteriology in the Medical College, was prevented by his duties at the Medical College from making any inspections during the year. In the working of a department, like that of vaccination, employing a large number of subordinates on small salaries and scattered over a wide area, experience has everywhere shown the necessity for unintermitting supervision, if the quality of the work is to be maintained at a high standard and if the falsification of returns is to be prevented. There was some increase in the total number of vaccine operations and a slight decrease, from 91·0 to 90·7, in the percentage of successful cases. Commenting on the remarkably high percentage of success in cases of re-vaccination in certain districts, the Government doubts the accuracy of the statistics and is inclined to believe that many cases of secondary vaccinations are classified in the accounts as those of re-vaccination. Instead, however, of trying to make the Vaccinators understand the difference between "secondary vaccination" and re-vaccination, as the Government suggests, it might be simpler to omit the former term altogether from the registers and returns; it finds a place in the vaccination returns of no other Indian Province, excepting in those of Madras; and as its use seems to give rise to confusion without adequate compensating advantage, the expediency of discontinuing it might be considered. As usual, calf-to-arm vaccination gave the most successful results; glycerinated lymph, prepared locally, and used in municipalities in 27,052 cases, came next with a percentage of 97·3 successful cases, followed closely by animal lymph in tubes and plates with a percentage of 97·0. The glycerinated lymph, locally prepared in different centres and used in 431,905 operations in local fund areas, yielded a percentage of only 87·4 successful cases. The use of humanized vaccine lymph has been entirely discontinued in the Madras Presidency; but this description of lymph still continues chiefly to be used in the other provinces of India and to yield high ratios of successful cases.

7. The Madras Presidency, which has so long successfully resisted invasion by *plague*, records 10,795 deaths from that disease during the year under report. In all cases, as stated in the Government review of the Report, "the infection was brought into this Presidency from territories beyond

the control of the Government of Madras." In carrying out his system of observation of areas imminently threatened by plague, the services of his trained staff of Certificated Sanitary Inspectors have been utilized by Colonel King in the detection of imported cases, and in preventing those from becoming centres of infection. It has thus been found possible, he says, to trace the origin and progress of epidemics with greater accuracy than in areas where such means are not adopted. He adds : " it may be accepted that experience in this Presidency shows that man causes the rat to suffer and not the rat man in the first place, that the area over which rats roam is usually small, and that recrudescence is by no means a natural feature of the disease, but a very natural result of apathy or too optimistic treatment of an indigenous infected area." Such experience is worthy of record, in view of the opinion expressed by some of the Delegates at the recent International Sanitary Conference held at Paris, regarding the part which rats play in the spread of plague.

8. The mortality ascribed to *fevers* and to *dysentery* and *diarrhœa* is fractionally less than in the previous year. Under the head of "all other diseases" no less than 45·7 per cent. of the deaths from all causes were registered. With the agencies available for the collection and record of vital statistics, registration of deaths according to their exact causes cannot reasonably be expected.

9. In Madras, as elsewhere in India, the want of funds is the main, although not the invariable cause of the slow progress in the execution of *Sanitary works*. Many schemes for providing towns with pure water supplies and drainage systems have been prepared in readiness for being put in hand when funds became available. From the Sanitary Engineer's Report, which follows that of the Sanitary Commissioner, the action of the Municipality of Guntur may be quoted as an instance of the refusal of a municipal town to provide itself with an urgently-needed water supply, even when funds for the execution of the undertaking are available. Owing to the water famine, which was the cause of severe distress to the inhabitants of Guntur, the Council was urged to construct immediately a brick culvert for conducting water from a spring into their town. "By this time, however, the water famine had abated, and the Council resolved not to carry out any portion of the permanent works. The Council is well able to afford the cost of the works proposed; and it is a matter for regret that the absolute necessity for the contruction of the permanent works has not been pressed on the Council." From which example it may be concluded that lack of zeal for the public good may sometimes take the place of lack of funds in retarding the execution of urgently-needed sanitary improvements.

21st July 1904.

No. 11.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1902.

More than a page of the Report is given to a somewhat prolix account of the rainfall for each month of the year and for each district of the Presidency; but from this no conclusion is drawn as to the influence the weather may have exercised on the public health. Judged by its vital statistics, the year was an unhealthy one; the deaths exceeding the births by 90,069. This result was due to an increase in the fatality of plague, which, of itself, accounted for upwards of a fourth part of the total mortality of the year.

2. The *birth-rate* of 34·16 per thousand of population was in excess of that recorded for each of the two previous years, and also of the mean for the ten years 1892–1901. The birth-rate of rural areas greatly exceeded that of urban areas; whilst the former was 35·23, the latter was only 27·09. The Sanitary Commissioner says: "The chief cause of the difference in the urban and rural birth-rates is due to defective registration." It might have been expected that fewer births would have escaped registration in towns than in the country; but the figures given would suggest an opposite conclusion. In the neighbouring Presidency of Madras the urban birth-rate exceeds the rural birth-rate; the former was 29·2 and the latter 28·1 per mille of the population for the year under report. The rural birth-rate in the Bombay Presidency exceeds the urban birth-rate by 8·14; the urban birth-rate in the Madras Presidency exceeds the rural birth-rate by 1·1. The difference is probably due rather to the mode in which registration is effected than to a reversal of the relative fecundity in urban and rural areas in the two Presidencies. The high ratio of still-born children in Bombay City has frequently been commented on, but never satisfactorily accounted for. In the opinion of the Health Officer it is due to "plague, the laborious occupation of females working under very trying circumstances in mills, factories, &c., and to the age at which women become mothers." A reference to the returns of vital statistics prior to the appearance of plague in Bombay proves conclusively that the high ratio of still-births in that city is not due to the prevalence of plague. Without going further back than 1895, the still-births registered during that year in Bombay City numbered 1,470 against 15,684 live births. This would give a ratio of upwards of nine per cent. The number was the same in the preceding year; yet the plague did not appear until towards the end of 1896. Nor can the high rate of still-births be due to the employment of women in factories, if, as stated in the Government review of the Report, "the number of women so employed is small." As to the last of the causes assigned for the high ratio of still-births, the age at which women become mothers in Bombay, we have met with no statistics which would show that this substantially differs from the ages at which women generally become mothers in other Indian cities.

3. The *death-rate* for the year under report rose to 39·04 from 37·12 in the preceding year, and exceeded the decennial mean by 2·62 per thousand of population. The increase was due to plague. The death-rate recorded for the urban population was 60·22, as compared with 35·85 for the rural population. In some towns death-rates of upwards of 150 per thousand were recorded. These high rates were attributed, in most part, to plague.

4. Of the *chief diseases*, *cholera* was in marked abeyance during the year. Only 3,229 deaths were attributed to it, the lowest number on record since 1886. No sufficient explanation has yet been given of the remarkable variations in the incidence of cholera from year to year. In this Presidency the returns show that the deaths caused by it were four times more numerous in the preceding year and fifty times more numerous in 1900 than in the year under report. Water being generally regarded as the medium by means of which cholera is communicated, it naturally comes to be asked why this should vary so greatly in purity from one year to the next.

5. *Small-pox*, like cholera, was less prevalent than during the previous year. The ratio of deaths due to it per thousand of population was only 0·12, as compared with 0·24, the mean for the previous five years. The highest death-rate recorded in this Presidency during any one year of the past 12 was only 0·52, figures which bear testimony to the efficiency of the Vaccination Department. During the year under review the number of primary vaccinations increased by 66,472; whilst the number of re-vaccinations decreased by 9,335. The percentage of success in primary operations, excluding those regarding which the results were not ascertained, was 98·91. Of the re-vaccinations, excluding "unknown" cases, the percentage of success was 82·78. In the Bombay Presidency, as in most of the other provinces of India, with the exception of Madras, humanized vaccine lymph is still chiefly used; and the results given by it are more successful than those obtained from any other kind. Only 70 cases were vaccinated with "glycerinated lymph," and the percentage of success in those was as low as 45·71. Lanoline paste gave a percentage of 84·18 successful cases. A favourable feature of the year's work is the large number of infants protected by vaccination. Of the infants available for vaccination, 71·85 per cent. were successfully vaccinated in the Presidency, excluding the Native States and Aden.

6. The mortality from *fever*, *dysentery*, *and diarrhœa* showed, as in the case of cholera and small-pox, a decrease as compared with that recorded in the preceding year. In short, but for the increase in the number of deaths due to plague, the year, as estimated by its death-rate, would have been a comparatively healthy one. From plague the number of deaths was the highest hitherto recorded in the Presidency, reaching as it did a total of 184,762, or 56,503 in excess of the previous year's number. Under the heading "other diseases" there was a marked decrease in the number of deaths; but this decrease is only apparent and is due to the deaths from *respiratory diseases* being now, for the first time, shown separately, instead of being included, as heretofore, in the total of those returned under the head of "other diseases."

7. The Sanitary Commissioner says: "Real sanitary progress has been at a standstill for some years past." The main cause of this was, doubtless, the disastrous epidemic of plague which, beginning so far back as September 1896, shows as yet no signs of abatement. Quoting from the Government Resolution on the Report: "Very few towns in the Presidency have escaped severe outbreaks of plague, which have burdened many with heavy debts." From which it may be understood that the direct cause of the retardation of sanitary progress is the exhaustion of funds resulting from expenditure on measures connected with the combat against plague.

8. The Sanitary Commissioner makes complaint of the frequency of the changes among his deputies, and very truly observes that "it is difficult for work to be properly supervised with such frequent changes." Although these changes are acknowledged by the Government to have been frequent, they are said to have been unavoidable.

9. Appended to the Sanitary Report is the Annual Report of the Health Officer of the Port of Bombay. The magnitude of the task with which the Port Officer had to deal may be realised from the statement that during the year 15,432 vessels of sorts, with crews and passengers numbering 701,964, were examined; whilst the clothing and bedding of 93,479 crew and passengers of outgoing and incoming vessels were disinfected. "Each individual who left the port was subjected to a rigorous and searching examination for any symptoms suspicions of plague. In addition to this examination, the personal clothing and bedding of such crew and passengers as came under the disinfection rules were thoroughly disinfected." At the recent International Sanitary Conference held at Paris, those of the Delegates who had made themselves acquainted with the measures adopted at Bombay for preventing the spread of plague infection from that port by sea were unanimously of opinion that these measures were carefully and successfully carried out.

21st July, 1904.

No. 12.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner for the Hyderabad Assigned Districts for 1902.

The most striking feature in the history of the public health for 1902 was the remarkable rise in the birth-rate. From 30·8 per thousand of population in the previous year, this reached 56·9 in the year under report, and was the highest recorded during the preceding 31 years. The history of other provinces furnishes many examples of similar increase in the birth-rate during a prosperous year immediately following a season of severe privation.

2. The abnormally high birth-rate was accompanied by a rise in the death-rate from 27·6 to 32·8 per thousand of population. Except for an outbreak of plague, the year was, however, a very healthy one. Cholera was almost absent from the province, only 16 deaths having been attributed to it; whilst the death-rate from small-pox only amounted to 0·1 per mille of population. The infant death-rate for the year under review was 620·1 per thousand in the case of male, and 523 in the case of female, children living, according to Annual Form No. IV. in the Appendix to the Report; but only 203·8 in the case of the former and 182·9 in the case of the latter, calculated on the number of births registered during the year under report. During the previous year the ratio of deaths amongst infants, calculated on the numbers living, was in the case of male children only 337·4, and in the case of female children 291·0, or not very much more than half the ratios for 1902. But any estimate of the comparative health of the two years, based on those figures, would be erroneous. In the one year, a smaller number (83,762) of children furnish the 16,485 deaths registered; and in the other year, a larger number (154,954) furnish the 29,992 deaths registered. In the case of both years alike, the death ratio is calculated on the same infant population numbers, with the inevitable result that the year under report, with its larger number of deaths of infants, shows a higher ratio of infant mortality than its predecessor. If, however, the calculation is made on the number of children born during each of the two years, the ratio of deaths amongst male children under one year of age will be found to be 203·8 in the year under report, as compared with 205·3 in the previous year; and amongst female children 182·9, as compared with 187·9. The positions of the two years are thus reversed in respect of the infant mortality recorded for each, and the year under report shown, as far as these figures can be taken as a safe guide, to have been healthier, instead of much more unhealthy, than the preceding year.

3. *Plague* was the only one of the *chief diseases* which showed a marked increase. The disease attained a firm foothold in the province and accounted for 4,188 deaths. The Civil Surgeon of one district states that "the disease was introduced by infected rats in goods wagons." Very clear proof would, however, be required before such a statement could be accepted, and none of any kind is given. As the resut of the experience gained in dealing with plague in Madras, the Sanitary Commissioner of that Presidency believes that, in the first instance, the disease is communicated by man to rats and not by rats to man. But the exact part played by rats in the dissemination of plague, is still uncertain. It is interesting to learn from the report "that although Banjaras (the gipsy tribe) have free communication with infected areas, not a case of death from plague had been recorded among them, thus clearly showing that the open-air life these people lead is a preventive against plague"; and also, it might be added, still further confirming the belief that the evacuation of plague-infected towns and villages is the most efficacious means yet discovered of bringing about the extinction of an outbreak of the disease.

4. The best proof that *vaccination* continues to make good progress and to fulfil its purpose in the province, is the steady decrease of the mortality from small-pox. On page 7 of the Vaccination Report for 1902–03, a statement is given of the ratios of mortality from small-pox in consecutive five-year periods, commencing from 1868–69. For the first of these periods the ratio of small-pox deaths per thousand of population was 2·02. During the following six periods the decrease has been uninterrupted, until for the last of them, that ending with 1902–03, it has fallen to 0·15. During the year under report, the number of vaccine operations performed shows an increase over that of the previous year of 20,646. This increase is said to have been due to the extrordinarily high birth-rate of 1902. The percentage of successful cases in primary vaccination was 96·8; whilst in re-vaccinations it was, as usual, very low in this province, having been only 16·5. This low percentage of success in re-vaccination cases may be due, in part, to the high quality of the primary vaccination, or to a stricter test having been applied before deciding a case of re-vaccination to be successful, than is usual in other provinces.

5. Regarding *sanitary works*, municipalities are said to have laid out a fair share of their income in their promotion. In rural areas, "useful work is gradually being done in providing wells, and land for purposes of nature, and in cleaning up village sites and filling up pools; but the progress is necessarily slow."

21st July, 1904.

No. 13.

Memorandum by the Army Sanitary Commission on the Administration Report of the Town of Calcutta for 1902–03.

During the past three years, or since the amended new Calcutta Municipal Act came into force in 1899, the Health Department has undergone reorganization. With the introduction of the new Act sanitary measures, under the stimulus of the plague epidemic, have been vigorously prosecuted. Owing to the recurrence of plague the public health of the year, as measured by the mortality, was bad. But for plague the death-rate would have been little, if at all, in excess of the mean recorded for the preceding decade.

2. The *birth-rate* of 14·2 per thousand of population, although considerably higher than that recorded for the previous year, when it was only 10·7, is still abnormally low. The expectation that

the division of the City into four districts would lead to improved registration of vital statistics has only to a limited extent been realised. The Health Officer has worked out an estimate of the birth-rates of the three Presidency towns, based on the number of women living in each between the ages of 15 and 40 years. Assuming the fecundity of the women at these ages to be approximately the same in each of these towns, he finds that 1·28 births are registered in Bombay, and 2·44 in Madras for every one registered in Calcutta. It further follows, he says, that if the registration in Calcutta were as efficiently carried out as it is in Madras, the birth-rate of the former would be 26·3, or nearly double the rate actually recorded. He recommends the adoption in Calcutta of the system of registration of births which has yielded so good results in Madras. The number of still-births was 4·9 per cent. of the total births including the still-born. In the City of Bombay, similarly calculated, it was 10·2, or more than double.

3. The *death-rate* recorded for the calendar year 1902 was 37·0 per thousand of population, as compared with 38·1 for the preceding year. The high death-rates of both years were due to the epidemic prevalence of plague. The infant mortality was very high ; a ratio of 338·6 deaths per thousand of population having been recorded for children of less than one year of age. Calculated on the number of births, this ratio was 491·0 per thousand ; that is to say, approximately half of the number of children born died.

4. Of the *chief diseases*, *plague* was the most destructive of life. According to the returns for the calendar year 1902, the deaths due to this cause numbered 7,278, equal to a ratio per thousand of population of 8·5. But there can be no doubt that the mortality from plague was greater than these figures would indicate. As the Health Officer observes, plague deaths were often falsely registered under other heads, as always happens during epidemics. The disease is said to have been of a more virulent type than during any of the previous epidemics, "the high case mortality being the subject of remark amongst both patients and practitioners." It is also stated that, as in previous years, there has been a wide-spread epidemic among rats, which reached its maximum in the beginning of January, and declined before the epidemic among human beings broke out. It is also added that "the fact tends to support the belief that rat mortality precedes the appearance of epidemic plague." The Sanitary Commissioner of Madras believes, on the contrary, as the result of experience in the Madras Presidency, that plague amongst human beings precedes its appearance amongst rats. The Chief remedial measures adopted in Calcutta have been disinfection of plague-infected rooms and huts, and the demolition of the latter under the plague regulations where disinfection could not be efficiently carried out. The attitude of the people towards the measures adopted is said to have been more friendly than in former years, and the amount of voluntary evacuation of plague-infected dwellings in some parts of the town striking ; whilst disinfections have been frequently applied for.

5. From *cholera* the mortality exceeded the mean for the preceding ten-year period and was only higher in two of those ten years. The death-rate from this cause amounted to 3·2 per thousand of population. For the Province of Bengal, as a whole, it was 2·02 ; and for the district of the 24-Parganas, which nearly surrounds Calcutta, 4·7. "Consequently," writes the Health Officer, "many cases were imported and formed foci of disease." No evidence is given in support of this assertion. The year having been one of epidemic prevalence of cholera in Bengal, it seems reasonable to conclude that the conditions which favoured the development and spread of the disease in the country surrounding Calcutta would not be inoperative in Calcutta itself. The mortality due to cholera in the 24-Parganas was certainly somewhat higher than in the town of Calcutta, a difference which might perhaps find its explanation in the greater purity of the filtered water-supply enjoyed by Calcutta, otherwise, so far as evidence is available for the support of either assertion, it might be contended with equal force that, instead of being conveyed from the country into the town, cholera was conveyed from the town into the country. Under similar circumstances of the synchronous prevalence of cholera in Madras and in the surrounding villages, the Health Officer of that City writes : "It has always been a discussion whether these villages were the means of introducing cholera into the city or *vice versa*."

6. *Small-pox*, to which 2,097 deaths were due in the preceding year, was credited with only 127 in the year under report. The results which have followed the abolition of the former Vaccination Department and the creation, in its place, of a system in accordance with which vaccination is carried on by Hospital Assistants acting under the four Health Officers are not considered to have been satisfactory. The number of vaccine operations performed has decreased by more than half as compared with the number performed in the preceding year. This decrease was, no doubt, partly due to the cessation of the epidemic of *small-pox* which had prevailed during the previous year, and which had induced a larger number of people than usual to get vaccinated. Moreover, the Health Officers thinks the work of vaccination suffered from the District Health Officers and the Hospital Assistants being new to the work, from constant changes amongst the staff, and from insufficient supervision.

7. The number of deaths attributed to *fevers* is less than the number recorded for the preceding year, and much less than the mean for the previous ten-year period. This decrease may not, however, be due to diminished prevalence of these diseases, but partly to improvement in the registration of deaths according to their causes. The Health Officer states that, "from the month of June, all the cases of death that occurred in the town were inquired into and were reported on by the Sanitary Inspectors, who are nearly all qualified medical men." The initiation of the system of inquiry may result in the issue of reliable returns of deaths in Calcutta, according to their exact causes, which may serve as a standard by which the accuracy of the returns of deaths according to their causes in other Indian communities may be approximately measured. Hitherto, although persistent attention to registration has by degrees secured comparatively correct returns of deaths, in so far as their numbers are concerned, there has been no corresponding improvement in the registration of deaths according to their causes. The inquiry instituted by the Health Officer has already elicited important information regarding the loss of life annually caused in Calcutta by phthisis. This loss, the Health Officer is satisfied, amounts to at least 10 per cent. of the total mortality from all causes.

8. *Drainage works* on a vast scale are in progress in Calcutta. The difficulties which surrounded the suburban drainage scheme have been overcome. The conversion of the intermittent into a continuous *water-supply* is being carried out. The presence of plague has added to the urgency of the need for *bustee improvement*. In the words of the Report: "In any scheme for a general improvement of the health of the city the re-modelling of bustees must occupy a foremost place. Overcrowding, want of air space, light and drains, and the absence of proper conveniences are the prominent faults in existing bustees, and these can be remedied only by wholesale measures."

21st July 1904.

No. 14.

Memorandum by the Army Sanitary Commission on the Administration Report of the Madras Municipality for 1902–03.

The sanitary history of the year is gathered from the few pages given to an explanation of the annual returns of vaccination and vital statistics. The year was healthier than either of its two predecessors; but its death-rate was still upwards of 40 per thousand of population, and somewhat in excess of the average of the ratios of the previous ten years. The rainfall was above the average by 5·42 inches; the total fall having been 54·44 inches. Excepting September and October, all of the other months recorded a temperature above the average.

2. Estimating its quality by the influence it has in protecting the people against small-pox, *vaccination* yielded better results in Madras than in the other great Indian cities. The death-rate from small-pox was only 0·1 during the calendar year 1902, and this was the average for the previous ten years. The number of cases vaccinated during the official year 1902–03 shows a decrease of 5,956 as compared with the number for the previous year. This is said to have been due to the smaller number of emigrant coolies vaccinated. Probably nearly all of those coolies would already have been vaccinated, or have had small-pox; so that the decrease in the total number of operations would take place under the head of re-vaccination. As a matter of fact, the cases of primary vaccination show not only no decrease, but a slight increase over the number recorded for the previous year. The percentage of successful cases in primary vaccination was 98·67, or slightly below that recorded in 1901–02. In re-vaccination there was a slight decrease in the percentage of successful cases from 70·59 in the previous year to 69·28 in the year under report. As pointed out in the Government review of the Report, the figures given in paragraph 139, with the object of comparing the percentage of successful cases following the use of different kinds of lymph, are not of much value, seeing that they do not distinguish between cases of primary vaccination and cases of re-vaccination. Whichever one of the three kinds of lymph mentioned is employed for re-vaccination would, almost certainly, yield a lower percentage of successful cases than the other kinds, provided that the latter were used only in primary vaccination. The large number of 1,020 prosecutions under the vaccination bye-laws testifies to the thoroughness with which these laws are enforced in the city of Madras; and to this is, doubtless, mainly due the comparative immunity from small-pox enjoyed by its inhabitants.

3. The *birth-rate* fell from 37·0 per thousand of population in the previous year, and from an average of 40·6 for the decade, to 34·8 in the year under report. This decrease is attributed to the high price of food and the prevalence of epidemic disease in 1901, "both of which seriously affect the health and vigour of the population, and therefore its fecundity." Moreover, the female, population of the city, once in excess, has steadily declined until, when the last census was taken, the male exceeded the female population by over five thousand. Without questioning the influence of these causes in tending to reduce the number of births, the Government is of opinion that the possibility of defective registration should be fully considered before other explanations of a decreased birth-rate are accepted.

4. A death-rate of 42·0 per thousand of population was recorded for the year. This, though less than the rate for the preceding year, when it was 46·2, is almost double what it might be, and what it may become, when the insanitary conditions to which the unhealthiness of Madras is known to be mainly due have been removed. Reduction of the death-rate is not to be looked for so long as parts of the town remain in the state described in paragraph 163 of the Report. "The streets are narrow and are literally used as latrines by children in the day and adults after dusk. Low-built, mud-walled houses, with no proper flooring, in such a dangerously polluted soil, must, of necessity affect the death-rate of the place. It is literally a case of 'excrement-sodden earth, excrement-reeking air, and excrement-tainted water,' and no wonder, therefore, that it is the home of cholera and other epidemic diseases."

5. From *cholera* and *small-pox* the town suffered comparatively little during the year, only 37 deaths having been caused by the former and 69 by the latter; but *fever* had ascribed to it 7,326 deaths, as compared with an average of 6,129 for the decade. As noted in the Report, however, no opinion as to the real causes that led to this high mortality is possible so long as registration remains in its present defective condition.

6. The City, as well as the Presidency of Madras generally, continued to enjoy remarkable immunity from *plague*. Of the 13 cases of the disease which occurred in the city during the year

not one was indigenous; all were imported. The passport system, which has been carefully maintained in force from the time that Madras was first threatened with an invasion of plague, has hitherto proved successful in preventing the disease from obtaining a permanent footing in the town.

7. The new *drainage works* were in progress during the year, and already upwards of fifteen lakhs of rupees have been expended of the thirty-two lakhs estimated to be required for their completion. The comparatively small sum expended in extending the *water-supply* to the whole of the city would appear to indicate that the progress of this work has not been repaid. The improvement of certain insanitary areas, to judge of their condition by the description given of them in the Report, is probably scarcely less urgent than the completion of the drainage and water-supply schemes.

21st July, 1904.

No. 15.

Memorandum by the Army Sanitary Commission on the Administration Report of the Municipal Commissioner of Bombay for the year 1902–03.

The Executive Health Officer's Report is so profusely interspersed with figured statements that the narrative portion of it is somewhat disjointed and difficult to follow. Some of the statements, if it was considered necessary to insert them, might have been relegated to the Appendix.

2. The year, as estimated by its record of vital statistics, was less unhealthy than any of its four immediate predecessors. Going back to 1896, the death-rate, which in that year was 40·71 per thousand of population, rose during each successive year until in 1900 it reached 96·55. In the following year it sank again to 76·66; and now in the year under report has fallen still further to 62·38.

3. The Health Officer considers the results achieved and the work done under the new scheme of birth and death registration proposed by him to have been satisfactory, In this scheme, which has been in operation for one year, the Health Officer himself occupies the place of Chief Registrar; and through his hands passes every detail regarding the record of birth and death statistics. The number of births registered during the year under report exceeded that registered during the preceding year by 4,079, the *birth-rate* rising at the same time from 17·42 to 22·67 per thousand of population. Yet, owing to the indifference of parents to the duty imposed on them under the Act to register all births, it is said that many of these still remain unregistered. The number of still-born children registered was 2,017 as compared with 2,153 in the previous year; but in consequence of the much larger number of births registered during the year under report than its predecessor, the proportion of still to live births is much less in the former than in the latter. In 1901 there were 16 still to every 100 live births; whereas in the year under report there were only 11·4 of the former to every 100 of the latter. These figures would appear to indicate that the abnormal proportion of still to live births hitherto recorded in Bombay City may have been in large part due to the incompleteness of the birth registration.

4. Whilst the birth-rate of the year showed a marked increase, the *death-rate* showed a still more marked decrease. From 76·66 per thousand of population in 1901 the latter fell to 62·38 in thye are under report. This decrease was chiefly due to less mortality from plague, cholera, remittent and relapsing fevers. From small-pox and measles there was a considerable increase in the number of deaths. The mortality amongst children under one year of age was, again, enormous, amounting as it did to 537·13 of every thousand births. The causes of this excessive infant mortality are not far, the Health Officer says, to seek. These causes he enumerates under nine heads, some of which affect the mother and others her offspring. Of this list of causes the incidence of none can be said to be peculiar to the mothers and children of Bombay City, although, as in other large cities of India, the prevailing insanitary conditions are doubtless more concentrated, and consequently more inimical to health, than in less densely populated places. On looking over the last Census Report, the Health Officer finds that 80 per cent. of the total population of the City live in tenements of one room with an average of four to five occupants. Such overcrowding, combined with poverty, is incompatible with healthy life all the world over; and so long as it is permitted to exist, little diminution of the bills of infant mortality need be looked for. During the year under report, the infant death-rates of the cities of Calcutta and Madras were, for the former 491·0, and for the latter 303·9, as compared with 537·13 for Bombay, per thousand births. Calculated on the number of children under one year of age when the last Census was taken in 1901, the death-rate for Calcutta works out to be 338·6, for Madras 395·1, and for Bombay 782·2. The enormous rate for Bombay the Health Officer explains to be due to the Census of 1901 having been taken in the month of March when plague was at its height, and when "the Census figures did not give an accurate return of the normal infant population." The death-rates calculated on the number of births registered during the year are certainly more likely to yield trustworthy results than those calculated on the numbers of children living when the last Census was taken; but in whichever way calculated the infant mortality is shown to be excessive.

5. Of the chief diseases, *cholera* was in comparative abeyance. It prevailed in a sporadic form throughout the year, no month being altogether free from it, and was the cause of a total of 75 deaths. Of these deaths only 10 occurred amongst persons whose birthplace was the City of Bombay.

6. *Small-pox* had 288 deaths ascribed to it, as compared with 159 in the previous year, and with 746, the average of the preceding five years. An Abstract of the monthly Returns of Vaccination is inserted in the Health Officer's Report; but no comment is made thereupon. It appears from this

return that the successful primary vaccinations numbered 13,292, and the successful re-vaccinations 363. The successful primary operations exceeded in number those of the previous year by only 347 ; whilst the children born exceeded those of the previous year by 4,070. Consequently, although the total number of children successfully vaccinated slightly exceeded that for the previous year, there was a large failing off in the *proportion* of successful vaccinations to number of children available.

7. The mortality from *fevers* shows a marked decrease, the deaths ascribed to them having been only 4,518 as compared with 7,921 in the preceding year. Of this total, 3,847 were due to the remittent type of fever. The number of deaths attributed to *enteric fever* increased to 89, or 27 more than in 1901, and 42 more than the average of the past five years. *Relapsing fever*, although far less fatal than in the previous year, was still accountable for 651 deaths. The Health Officer states that the fever mortality rose and fell with the mortality from plague ; and this suggests that the number of deaths ascribed to plague is probably less than the actual number.

8. *Plague* was credited with 13,820 deaths, as compared with 18,736 in the previous year. The Health Officer considers the year to have been an unique one in the history of plague epidemic in Bombay. "Considering the fact," he writes, "that the population of Bombay was full in 1902, and all plague measures were voluntary, and that cholera, small-pox, and measles were to some extent prevalent in the city, it would appear that the mortality of 1902 is the lowest that was recorded in any previous epidemics (with the same unfavourable circumstances)." But sanguine anticipations regarding the future course of plague in Bombay do not appear to derive much support from an examination of the mortality returns recorded on page 174 of the Report. The question of the part played by rats in the spread of plague infection is still unsettled. Whether rats convey infection to man or man to rats is, according to the Health Officer, "only a matter of conjecture" ; but in a subsequent paragraph of his Report it is stated that "it is communicable from man to man by direct and indirect infection. It is communicable from man to rats and through rats to man." As to the most effectual measures for extinguishing the disease, he says : "The only really valuable method we have of checking the spread of plague is by removing the infected to hospital, or thoroughly isolating them and the contacts to an uninfected locality and preventing any communication with infected areas. In no case where this has been thoroughly done has plague continued to spread." The question, however, is whether this is practicable ; and this question, as regards Bombay, has been definitely answered in the negative. What follows may be taken as evidence of the impracticability of carrying out such a proposal. "If," the Report continues, "we could remove 300,000 people from infected houses in Bombay for six months, isolate cases as they occur, keep the vacated houses empty, thoroughly disinfect them, demolish the insanitary quarters, prevent immigration from infected areas, plague would be under control and soon disappear." Even if the peculiar nature of the site of Bombay and the greatness of the popnlation to be dealt with did not offer almost insuperable difficulties to the enforcement of such a series of drastic measures, the passive resistance, or active hostility, of the people towards them have already demonstrated the futility of attempting to carry them into effect.

9. A brief account is given of the progress of sanitary improvement during the year. The drainage works are being pushed forward towards completion ; and what, in the present emergency, is perhaps a still more urgent measure, the demolition of ill-ventilated houses is being actively proceeded with. The difficulty will be to provide the evicted inmates with new and more sanitary dwellings.

21st July, 1904.

A. GODLEY,
Under Secretary of State for India.

INDIA OFFICE,
31st October, 1905.

REPORT.

The present Report on Sanitary Measures in India during the year 1903 is prepared for presentation to Parliament. It contains chapters on the health of the European and Native troops, on the health of prisoners in jails, and on the health of the general population ; it also contains chapters on vaccination, on medical institutions, including medical schools and lunatic asylums, and a chapter on sanitary works. Appended to the Report are abstracts of reports by the three principal Sanitary Commissioners in India, and memoranda by the Army Sanitary Commission in England reviewing the several Sanitary Reports for India.

I.—EUROPEAN ARMY.

Sickness and mortality in 1903.

There was a marked improvement in the health of the European troops serving in India during the year 1903 ; the daily sick and invaliding rates were much lower than in the previous year, and the death-rate improved. On an average strength of 70,445, the admissions into hospital were in the ratio of 1,033 per 1,000, against 1,078 in 1902, the daily sick-rate fell from 66 to 63, and the death-rate from 14·68 to 13·05. The invaliding ratio (29) was lower by 8 per 1,000, so that the total loss by death and invaliding was equal to 42 per 1,000, a decrease of 10 per 1,000 on the previous year.

The following statement shows the relative extent of sickness and mortality among European troops in the four Commands and Burma District during 1903 and the previous year :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Daily Sick.	Deaths.	Invaliding.	Total Loss.
Bengal	1903	21,860	977	63	15·46	30	45
	1902	17,765	1,063	71	15·31	36	51
Punjab	1903	17,997	1,007	57	12·56	25	38
	1902	15,036	1,050	62	14·07	35	49
Madras	1903	9,375	1,071	73	7·79	34	42
	1902	8,422	1,009	66	7·96	36	44
Burma District	1903	3,616	1,172	73	13 00	30	43
	1902	3,675	1,317	81	11·96	54	66
Bombay ...	1903	15,990	1,115	65	12·32	33	45
	1902	14,404	1,125	67	19·58	43	63
INDIA ...	1903	70,445	1,033	63	13·05	29	42
	1902	60,540	1,078	66	14·68	37	52

It will be seen from the above statement that Madras and Burma had the highest sick-rates, and Bengal and Burma the highest death-rates. In regard to mortality, there was an improvement in all the Commands except Bengal and Burma district, where the death-rates rose from 15·31 and 11·96 respectively, to 15·46 and 13·00.

The chief causes of sickness in the whole European Army were venereal diseases and ague, the former yielding a ratio of 247 per 1,000 against 281 in 1902, and the latter 243 per 1,000 against 247. Forty-seven per cent. of the total sickness resulted from

these two causes. Enteric fever, as usual, was the chief cause of mortality, the death-rate from it being 4·19, slightly lower than the ratio of the previous year (4·29). Thirty-two per cent. of the total deaths were due to this cause.

Groups of stations.—The following table shows the sickness and mortality among the European troops according to groups :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	975	1,668	103	15·38
Burma Inland	2,408	1,005	65	11·63
Bengal and Orissa	1,912	1,226	76	15·17
Gangetic Plain and Chutia-Nagpur	6,831	947	67	16·98
Upper Sub-Himalayan	13,261	1,044	63	15·47
North-Western Frontier, Indus Valley, and North-Western Rajputana.	4,742	1,098	57	11·60
South-Eastern Rajputana, Central India, and Gujarat.	6,097	1,315	73	20·01
Deccan	10,262	1,090	66	8·97
Western Coast	1,672	900	61	8·37
Southern India	3,573	1,093	74	9·80
Hill Stations	9,921	744	49	8·87
Hill Convalescent Depôts and Sanitaria ...	3,673	1,027	69	10·89

Of the above 12 groups, nine returned a higher daily sick-rate than that for the European Army as a whole, and in five groups the death-rate was greater. The most unhealthy groups, judged by the daily sick-rate, were Burma Coast, Bengal and Orissa, Southern India and Central India, with daily sick-rates of 103, 76, 74, and 73 per 1,000 respectively.

Of the stations with a strength of over 1,000, the highest death-rates were those of Peshawar (22·15), Meerut (19·65), Ranikhet (19·06), Umballa (18·95), Sialkot (18·41), Mhow (17·94), and Fort William (13·70).

Cholera.—Cholera was very prevalent during the year, and among the European troops 81 cases were recorded with 57 deaths, against only three cases which proved fatal in 1902. All the Commands except Madras were affected but the deaths were reported from only 16 stations.

Small-pox.—Among the whole of the European troops in India there were during the year under notice 68 cases of small-pox with eight deaths. In the previous year there were 23 cases and four deaths.

Fevers.—From intermittent fever the admission-rate per 1,000 among the European troops was slightly less than in 1902, viz., 243 against 247, and the death-rate fell from 0·50 in 1902 to 0·34 per 1,000. How far this slight improvement is due to the measures taken for the destruction of infection-bearing mosquitoes is uncertain. The Sanitary Commissioner, however, says : "There can be no doubt that the efforts put forth during the past year have been far more general, more complete, more consistently and energetically maintained, and better organized than heretofore. At the same time signs are not wanting that in many respects the work has yet to be developed in its range and in completeness before we can hope for measurable results."

Enteric fever was more prevalent than in the previous year. The admissions rose from 1,012 or 16·7 per 1,000 of strength to 1,384 or 19·6, and the deaths from 260 to 295, but the death-rate fell slightly from 4·29 to 4·19 ; "the case mortality was lower to the extent that in every 1,000 cases 43 more men recovered in 1903 than in the previous year." Of the Commands Bombay again recorded the highest mortality under this head, viz., 4·63, followed by the Punjab and Bengal with ratios

of 4·39 each. Among the larger stations with an average strength of over 1,000, Meerut returned a death-rate from this fever of 11·59, Sialkot 10·04, Peshawar 9·85, Umballa 9·79, Poona 8·07, Mhow 7·69, Agra 5·43, Lucknow 4·81, Rawalpindi 4·69, and Ranikhet 3·31. As usual, young and unacclimatised soldiers were the chief sufferers; among those from 20 to 25 years of age the death-rate was 6·37 per 1,000 against 7·06 in 1902, while among men between 25 and 30 and from 30 to 35 the mortality was 2·58 and 1·45 per 1,000 respectively. Among men of less than one year's residence in India the death-rate from this fever was 7·95 per 1,000, among men between one and two years 4·88, and among men between five and ten years' service 3·28 per 1,000. Of the total 295 deaths from enteric fever, 74 per cent. occurred among men between the ages of 20–25, and 21 per cent. among men between the ages of 25–30.

Bowel Complaints.—The admissions from dysentery and diarrhœa among the European troops were in the ratio of 30 per 1,000 of strength, or 3 per 1,000 less than in 1902. The mortality from dysentery was in the ratio of 0·70 against 0·69 in the previous year. As regards the Commands the highest place is usually occupied by the Bengal Command, but in 1903 Burma district returned the highest admission-rate from dysentery.

Abscess of the Liver.—From abscess of the liver there were 92 deaths, giving a ratio of 1·29 per 1,000 of strength, against 112 or 1·85 in 1902.

Plague.—There were 12 cases of plague among the European troops and two deaths, against four cases and one death in 1902. The disease was prevalent among the general public in every Command area, but it was only in those of Madras and Bombay that the troops were attacked.

Venereal Diseases.—Venereal diseases ranked first in the list of causes of admission to hospital, and first in the causes of invaliding. They were the cause of nearly 24 per cent. of the total sickness during 1903, and of $10\frac{1}{4}$ per cent. of the invaliding of the European Army of India. The admission-rate from venereal diseases per 1,000 of strength was 247·0, a lower rate than had been recorded for 24 years, and less than half the maximum rate of 522·3 recorded in 1895. Of the Commands, Burma district returned the highest ratio, viz., 346·2 followed by Madras 334·7 against 343·4 in 1902; Bombay 259·6 against 286·7; Bengal 251·1 against 299·4; and the Punjab 176·1 against 217·5. The number of men constantly sick in hospital from these diseases was 1,569 against 1,431 in the previous year; and the average stay of a case in hospital was about 33 days. The deaths from these diseases numbered 10 and the invalidings 213, against 15 and 310 respectively in 1902.

Invaliding.—The loss to the whole European Army by invaliding during 1903 amounted to 2,063 men, equal to 29·29 per 1,000 of strength, against 2,255 or 37·25 in 1902. By Commands the invaliding rates ranged from 34·45 in Madras to 25·39 in the Punjab and there was a reduction in each as compared with the previous year. As regards the influence of age and length of residence in India upon invaliding, 50 per cent. of the total number invalided were under 25 years of age against 35 per cent. in 1902, while 30 per cent. against 17 were of less than two years' service, and 64 per cent. against 48 were of less than five years' service.

II.—NATIVE ARMY.

Sickness and Mortality in 1903.—The health of the Native Army of India during 1903 was exceptionally good. The admission and constantly sick rates were the lowest on record, and the death-rate was lower than in any previous year, if the mortality among men absent on furlough and sick leave be disregarded.

The ratios of sickness and mortality among Native troops in the Commands during 1903 and the previous year are given in the following table :—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Daily Sick.	Deaths.
Bengal	1903	29,338	615	22	8·21
	1902	26,652	629	25	8·03
Punjab	1903	40,582	692	26	10·60
	1902	43,486	746	27	12·76
Madras	1903	18,679	484	21	7·33
	1902	18,359	567	24	13·89
Burma District	1903	6,502	730	25	7·54
	1902	5,862	937	30	6·14
Bombay	1903	25,471	757	29	13·47
	1902	24,371	856	30	11·65
INDIA	1903	124,660	662	25	10·04
	1902	124,231	718	27	11·16

Of the Commands, Bombay was the most unhealthy in 1903, followed by the Punjab. Pneumonia continued very prevalent in the Punjab and Bombay Commands, and the death-rates from it were 4·41 and 4·20 per 1,000 respectively.

The chief cause of sickness in the Native Army was ague, which contributed 37 per cent. of the total admissions. Compared with the previous year there was some increase in the admission-rates from influenza, cholera, enteric fever, and tubercle of the lungs, and in the death-rates from cholera and enteric fever, but there was a diminished prevalence of all the other chief causes of sickness and mortality. From cholera the admission-rate rose from 0·2 per 1,000 of average strength in 1902 to 1·1, and from enteric fever from 0·4 to 0·6. From venereal disease the admission-rate was 24·5, against 247·0 among European troops.

Pneumonia was as usual the chief cause of death in the Native Army, and contributed 30·5 per cent. of the total deaths, the death-rate being 3·06 per 1,000 of average strength, against 3·71 in 1902. From this disease the mortality among the Native soldiers was more than five times as great as that among European troops (0·57 per 1,000). From fevers of all kinds the death-rate was 1·77 per 1,000, against 4·68 per 1,000 among the European troops. From ague, remittent and simple continued fevers the deaths among the Native troops were in the ratio of 1·55 per 1,000, while among the European troops the proportion was 0·75. On the other hand, the death-rate from enteric fever among the Native troops was only 0·22 per 1,000, as compared with 4·19 among the European troops.

From cholera there were 80 deaths in the Native Army, equal to 0·64 per 1,000 of strength, as compared with 15 or 0·12 in 1902.

During 1903 there were 184 cases of plague among the Native troops with 115 deaths, against 192 cases and 95 deaths in 1902.

Groups of stations.—The following statement gives the principal statistics of the Native Army, arranged in geographical groups, for 1903 :—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Daily Sick.	Deaths.
Burma Coast and Bay Islands	1,254	806	24	7·18
Burma, Inland	4,133	771	27	7·98
Assam	1,340	827	33	9·70
Bengal and Orissa	2,474	759	26	4·85
Gangetic Plain and Chutia-Nagpur	6,857	490	21	8·02
Upper Sub-Himalayan	15,987	575	21	12·76
North-Western Frontier, Indus Valley, and North-Western Rajputana.	17,283	788	28	10·13
South-Eastern Rajputana, Central India, and Gujarat.	12,202	829	29	10·74
Deccan	16,596	576	21	7·83
Western Coast	2,047	701	33	12·70
Southern India	7,170	591	28	7·53
Hill Stations	21,676	760	34	13·06

In six of the 12 groups the daily sick-rate was higher than that for the whole Native Army, and in three the mortality was greater. The highest mortality was recorded by the Hill Stations group, viz., 13·06, of which pneumonia contributed 4·71. In 1902 this group returned a death-rate of 13·70.

There were only two stations with an average strength of over 1,000 in 1903, viz., Mian Mir and Ferozepore, and their death-rates were 29·17 and 22·97 respectively. At the former station just over one-half of the mortality was due to cholera and a quarter to pneumonia ; and at Ferozepore one-third of the death-rate was due to pneumonia.

III.—GENERAL POPULATION.

The climatic conditions of the year 1903 were generally favourable ; the harvests were on the whole good, and food prices were slightly lower than in 1902 ; but the health of the people was less satisfactory, chiefly owing to the prevalence of cholera and plague.

The mean birth-rate of the population under registration was 38·96 per 1,000, against 39·38 in 1902, the birth-rates of the several provinces ranging from 46·13 per 1,000 of population in the United Provinces to 26·51 in Coorg. The mean death-rate for the whole of India was 34·7 per 1,000 against 31·49 in the previous year, the death-rates ranging in the various provinces from 49·0 in the Punjab to 22·2 in Madras Presidency. Of the chief diseases cholera was more prevalent, and the deaths rose from 224,135 in 1902 to 312,854. Coorg and Ajmer Merwara were quite free from the disease ; but in all the other provinces except Madras and Assam the mortality was higher than in the previous year. The mortality from small-pox, which had been steadily rising, fell from 115,603 to 93,693. From fevers the number of deaths was higher than in 1902 by 167,285, the total being 4,459,237 or 56 per cent. of the total deaths. Deaths from dysentery and diarrhœa rose from 236,869 to 273,459. The year 1903 was the eighth of the present epidemic of plague in India, and in each year except 1900, there has been a steady rise in the mortality from the disease. A further increase of 256,601 deaths occurred in the year under notice, the total being 701,894. Of these 281,269 occurred in Bombay, 215,462 in the Punjab, 84,499 in the United Provinces, and 65,680 in Bengal.

The deaths from the chief diseases and from all causes in the several British provinces were as follows :—

PROVINCES.	CHOLERA.		SMALL-POX.		FEVERS.		DYSENTERY AND DIARRHŒA.		PLAGUE.		DEATHS FROM ALL CAUSES.		
	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.	Total Deaths.	Ratio per 1,000.

Bengal.

The year 1903 was not generally a healthy one in Bengal. The birth-rate per 1,000 of population fell from 40·14 in the previous year to 39·00, which was made up of district ratios ranging from 50·91 in Gaza to 15·54 in Calcutta. Only in 20 districts did the birth-rate exceed 40 per 1,000, and it was lower in 31 districts and higher in 15 as compared with the previous year. In spite of an increase in deaths from cholera and plague, there was a slight falling off in the total mortality (from 2,488,428 to 2,481,149), and the death-rate remained nearly the same, viz., 33·33 against 33·43. Among the districts the highest rate (48·73) was recorded by Saran, and in 23 other districts out of 45 the provincial rate was exceeded.

Taking the chief diseases seriatim, there was a serious rise in the mortality from cholera, the number of deaths being 203,405 or 2·73 per 1,000, against 150,971 or 2·02 in 1902. The disease was present in every district, and it attacked over 13 per cent. of the villages against 11 per cent. in the previous year. Among other precautionary measures the disinfection of wells was resorted to in 25 districts which more or less suffered from cholera, and it is generally said to have been attended with beneficial results, although in Puri, where the wells were disinfected before the commencement of the cholera season, the second highest death-rate (6·31) from the disease among all the districts was recorded. Champaran district in the Patna division was the worst sufferer, the death-rate being 7·69.

Small-pox greatly abated during the year, and the deaths fell from 57,430 or 0·77 per 1,000 to 30,459 or 0·40. But though the mortality was smaller than in the two preceding years it was still very large, and energetic measures are being taken to push on vaccination as much as possible. The disease was present in all the districts except Chittagong, but the death-rate only exceeded 1 per 1,000 in three districts, the highest being 1·64 in Sonthal Parganas in the Bhagalpur division. Out of the total small-pox deaths over 61 per cent. occurred amongst children under ten years of age.

Fever was less prevalent than in the preceding year, the mortality from it amounting to 1,654,941 or 22·23 per 1,000, against 1,721,921 or 23·13 in 1902. As regards the relative intensity of the disease in each district, Dinajpur suffered most with a ratio of 37·19 per 1,000 against 37·09 in the preceding year, and in 22 other districts the provincial death-rate was exceeded. Steps were taken for the organization by private enterprise of agencies for the destruction of mosquitoes, but little was done in this respect. "The people generally," the Lieutenant-Governor says, "even those who are educated, including Europeans and many medical officers, do not yet appear to have grasped the importance of this measure." There was a large reduction in the number of packets of quinine sold during the year, which was probably due to the prevalence of fever being somewhat less than in the previous year.

Dysentery and diarrhœa were slightly less prevalent, but the death-rate (0·76) remained the same. As compared with the previous year the incidence of these diseases was lighter in 29 and heavier in 17 districts. The urban mortality was much greater than that in rural areas, and must, the Sanitary Commissioner fears, continue to be so while overcrowding with its attendant evils is allowed to exist.

Nearly twice as many deaths were recorded from plague as in 1902, the number having risen from 32,967, equal to a ratio of 0·44 per 1,000 of population, to 65,680 or 0·88. The disease was present in 29 districts against 24, Saran being the worst sufferer with a death-rate of 10·61, followed by Calcutta 9·69, Patna 7·19, and Shahabad 3·87, against 5·68, 8·58, 1·71, and 1·16 respectively in the preceding year. The measures adopted in dealing with the disease were disinfection and evacuation, but generally the attitude of the people towards the disease was one of marked apathy.

The municipality of Calcutta recorded a birth-rate of 15·5 per 1,000 of population, which is an improvement on the previous year's rate of 14·2, but still far below the actual facts. With a view to improving birth registration a new system was experimentally adopted in one district of the town, and the result showed an increase of 51 per cent. above the average of the past three years. It is proposed to extend the system to the other districts. The death-rate fell from 37·0 to 35·1. Excluding plague deaths this ratio is reduced to 25·4. Cholera was very prevalent in the first half of the year, but the year's mortality was somewhat below the average. The mortality from small-pox was comparatively low, as was also that recorded under fevers.

United Provinces of Agra and Oudh.

The year under notice was an unhealthy one in the United Provinces of Agra and Oudh. A birth-rate of 46·13 was recorded, which was the highest among the provinces of India, and exceeded the death-rate by 5·85 per 1,000. In 25 districts the birth-rate was above, and in 23 below, the provincial mean, the highest being 56·08 in Shahjahanpur, while ten other districts returned rates of over 50 per 1,000. The number of registered deaths rose from 1,552,046 or 32·54 in 1902 to 1,920,903 or 40·28, which was composed of district rates varying from 55·90 in Hamirpur to 30·94 in Mirzapur. Fevers, measles, and plague were the chief causes of the increased mortality. The last-named disease was exceptionally virulent and accounted for more deaths than plague.

Under all heads of disease the mortality was higher than in the previous year. Cholera deaths rose from 25,160 or 0·53 per 1,000 to 47,159 or 0·99. The increase was mainly due to an outbreak of the disease at the time of the dispersion of the pilgrims at the great fair (Kumbh Mela) at Hardwar. During the period of the fair only 11 cases of

cholera occurred. On the 13th of April, the great bathing day, some 400,000 people were present, and by the 16th about three-fourths had dispersed and the general sanitary arrangements were being broken up. On this day, it is reported, the disease broke out with great virulence among the Bairagis, a sect of fakirs, and from them it spread to other pilgrims still remaining in and about Hardwar, who carried it to other parts of the United Provinces and to the Punjab.

From small-pox the deaths rose from 4,976 or 0·10 per 1,000 in 1902 to 21,950 or 0·46. The districts which suffered most are situated in Oudh, where vaccination has hitherto been more backward than in other parts of the provinces. Of the total small-pox deaths over 88 per cent. occurred among children under ten years of age.

The deaths attributed to fever rose from 1,169,102 or 24·51 per 1,000 to 1,318,519 or 27·65. In many localities attempts have been made by civil surgeons to encourage the destruction of mosquitoes and their larvæ by the addition of kerosene oil to stagnant pools of water, and increased efforts were being made to improve surface drainage and to bring quinine more generally within the reach of the poorer classes.

The number of deaths recorded under dysentery and diarrhœa rose from 27,915 or 0·58 per 1,000 in 1902 to 40,660 or 0·85. As usual Garhwal headed the districts with a death-rate of 10·02, and in 15 other districts the provincial rate was exceeded.

The mortality from plague was more than twice as great as in the previous year, the total being 84,499 or 1·77 per 1,000 as compared with 40,223 or 0·84 in 1902. Deaths from the disease were reported from all but seven of the 48 districts. The highest rates recorded in the districts were 11·10 in Cawnpore, 9·07 in Allahabad, 6·69 in Lucknow, 6·19 in Ballia, and 6·04 in Unao, while in ten districts the number of fatal cases was below ten.

Punjab.

The Punjab was the unhealthiest province in India in 1903. The vital statistics of the province were vitiated to a considerable extent by the effects of plague. The birth-rate was 42·9 per 1,000 of population, which is only a fraction less than that recorded in the previous year. According to districts the birth-rates ranged from 50·1 in Sialkot to 17·3 in Simla. The death-rate was 49·0, and exceeded the rate of the previous year by 4·9 per 1,000. Among the districts Gujranwala had the highest death-rate of 96·3 per 1,000, of which more than two-thirds were due to plague. Nine other districts recorded death-rates of over 50 per 1,000, and in each of these plague was very virulent.

Almost every disease showed an increased mortality rate. In the two previous years the province was almost free from cholera, but in 1903 the disease prevailed in epidemic form and claimed 14,688 victims, equal to 0·73 per 1,000 of population. The province was free from the disease during the first three months of the year. In April, however, after the Hardwar Fair in the United Provinces, cases began to occur in different parts of the province among pilgrims returning from the fair, and the epidemic reached its height in July, when a mortality of 6,184 was registered. The disease declined considerably in the following months, until in December there were only two deaths from it. The total mortality was small compared with previous Kumbh fairs at Hardwar, a result which the Lieutenant-Governor says, "appears to have been largely due to the prompt and effective measures adopted by the district staffs of the province to cope with and obviate a spread of the disease." The districts of Ferozepore, Lahore, Ludhiana and Umballa were most affected, and contributed 62 per cent. of the total cholera mortality.

The mortality from small-pox was 15,635 or 0·78 per 1,000, being a fraction higher than the rate recorded for the previous year. The disease was present in all the districts. Rawalpindi was the chief sufferer with a death-rate of 2·95 per 1,000, and Kangra which is the best vaccinated district had as usual the lowest rate. Of the total small-pox deaths 80 per cent. occurred among children under ten years of age.

From fevers the death-rate rose to 25·33, being 1·78 higher than in 1902. Fourteen districts recorded a mortality in excess of the provincial rate, and in several of these the high mortality was attributed to unusual rainfall and heavy inundations. As yet little has been done in the destruction of mosquitoes. Trial measures were carried out in Gujranwala and Gujrat districts, but the severe prevalence of plague in the former interfered with the operations. Quinine was as usual distributed gratuitously in many of the districts.

The mortality from dysentery and diarrhœa rose slightly, from 0·70 per 1,000 in 1902 to 0·82, a ratio which was exceeded in nine districts, the highest being 2·11 in Umballa.

Plague spread considerably during the year, and in some of the most fertile districts the havoc played by the disease is stated to have been terrible. The deaths rose from 171,302 or 8·52 per 1,000 to 205,462 or 10·22. Among districts Gujranwala lost 63 per 1,000 of its population from the disease, Jullundur 28·6, Amritsar 25·6, Lahore 20·7. It is reported that 327,357 inoculations were performed during the year, and that, although the results varied in different areas, in the province as a whole the liability of the uninoculated to death was two and a half times greater then the liability of the inoculated.

North-West Frontier Province.

In the North-West Frontier Province the birth-rate fell to 31·6 from 33·6 in 1902, and the district rates ranged from 56·2 in Dera Ismail Khan to 29·7 in Peshawar. The deaths increased by 7,915, and the death-rate rose from 24·4 to 28·4. The year 1903 cannot therefore be considered a healthy one.

From nearly all the chief diseases the mortality was greater than in the previous year. In 1902 the province was entirely free from cholera, but in the year under notice 1,354 deaths from the disease were recorded, being equal to a ratio of 0·68 per 1,000 of population. The epidemic is said to have been traceable to the importation of cases from the Khumb Mela at Hardwar, in the United Provinces. From small-pox the death-rate rose from 0·54 to 1·35 per 1,000. Of the total 2,694 deaths from the disease, 2,500 were children under ten years of age. The death-rate from fevers was 2·45 per 1,000 higher than in 1903, and that from dysentery and diarrhœa slightly lower. There was very little plague in the province, the number of deaths being only 49 against 4 in the previous year, and all these occurred in the Hazara district.

Burma.

In Lower Burma the birth-rate in 1903 was 33·54 per 1,000 against 31·57 in the preceding year, the improvement in registration being attributed to the closer supervision now being exercised by the health officer and his assistants. In Upper Burma the registration of births is still confined to a few towns, and the average birth-rate was 37·48 against 38·07 in 1902. In both parts of the province there was an increased mortality which was ascribed to the unhealthiness of the year owing to abnormally heavy rains following a prolonged drought. In Lower Burma the death-rate rose from 21·16 to 24·13, and in Upper Burma from 17·29 to 21·80 per 1,000, the increases being mainly due to fevers and bowel complaints.

Cholera was very prevalent during the year. In Lower Burma the death-rate rose from 0·33 to 0·97, and in Upper Burma from 0·02 to 1·00 per 1,000. The disease prevailed in every district except Tavoy, and Mergui was practically free, as only three deaths were recorded. It was most severe in Akyab, where the death-rate reached 3·07 per 1,000.

Small-pox was the only one of the chief diseases which was less fatal than in the previous year. The death-rate was 0·23 per 1,000 in both parts of the province. Of the total 1,920 deaths 42 per cent. were children under ten years of age.

Fever as usual was the chief death cause of the province. In Lower Burma the deaths were in the proportion of 10·14 per 1,000 against 8·80 in 1902, and in Upper Burma 7·63 against 6·37. The Sanitary Commissioner attributed the increase to "the enhanced rainfall and consequent greater humidity of the atmosphere, the more extended water logging of the soil, and the increased rain-water lodgments on the surface." In the matter of the prevention of fever no systematic measures were carried out generally for the destruction of mosquitoes, but municipalities utilised their conservancy establishments in filling in pits and draining unnecessary collections of water.

The death-rate from dysentery and diarrhœa in Lower Burma was 1·61 per 1,000 against 1·30 in 1902, and in Upper Burma 0·39 against 0·23.

There was no case of indigenous plague during the year, but there were ten cases of imported plague, five of which were detected in the port of Rangoon, one in the town of Rangoon, and four at Moulmeim. Precautionary measures were taken to prevent the disease spreading and "the successful resistance to the invasion of plague from infected centres justifies," the Sanitary Commissioner states, "the stringency with which the rules in force have been worked."

Central Provinces and Berar.

Berar having been amalgamated with the Central Provinces since October, 1903, the vital statistics of the provinces are now treated together. For the year under notice the combined birth-rate was 45·11 per 1,000 of population against 50·17 in 1902. All the districts but two registered a lower birth-rate than in the previous year. On the other

hand the death-rate was higher, which was to some extent due to plague, though apart from this disease the year was not so healthy as 1902. The total deaths numbered 443,697 or 35·52 per 1,000 against 341,430 or 27·33. The increase was very general, being spread over all the districts but three in the Central Provinces.

The number of deaths recorded from cholera was 437, equal to a ratio of 0·03 per 1,000, against 44 or ·003 in 1902. There were two outbreaks of the disease, one at Kutni-Murwara, causing 143 deaths, and another which started in Wun and spread to Chanda district, causing 189 deaths.

The mortality from small-pox was considerably less than in 1902, the number of deaths having fallen from 4,621 or 0·37 per 1,000 to 2,130 or 0·17. The Sanitary Commissioner states that the district reports show that a number of the deaths attributed to measles and chicken-pox were probably due to small-pox. Of the total 2,130 deaths 73 per cent. occurred among children under ten years of age.

Fevers were more prevalent and fatal than in the previous year, and the deaths rose from 179,242 or 13·36 per 1,000 to 190,707 or 15·27. The increase, however, was entirely in the Central Provinces, as Berar registered 5,862 fewer deaths than in 1902. The Sanitary Commissioner states that with few exceptions the districts in the Central Provinces in which plague prevailed recorded an increase of fever mortality, but in the Berar districts in which plague prevailed there was a considerable decrease in fever mortality. Little was done during the year in the way of anti-malaria crusades, as the time of the Civil Surgeons was fully taken up with plague.

The death-rate from dysentery and diarrhœa rose from 1·69 per 1,000 to 2·66, the increase being attributed to the heavy rainfall of the year following a long dry season, thus rendering the people liable to these forms of bowel disease.

Plague was prevalent in many parts of the province during the year, and the deaths rose from 5,249 to 51,514 or 4·13 per 1,000. There were two epidemics, one in the earlier and another in the later months of the year. The disease raged with special violence in the districts of Nagpur, Jubbulpore, Hoshangabad, Nimar Narsinghpur, Amraoti, Akola and Buldana. The attitude of the people with regard to plague is reported to have undergone a change for the better; they understand the value of evacuation and the desirability of temporarily excluding arrivals from affected areas, but inoculation and disinfection are said to be unpopular.

Assam.

The general health of the population of Assam was better than in 1902. In the area under registration with a population of 5¼ millions the births represented a ratio of 35·57 per 1,000, which is a small improvement on 34·21 in the previous year. As usual Goalpara district had the highest birth-rate (43·22), followed by Sylhet, these being the only two districts in which the provincial rate was exceeded. The registered death-rate was 26·55 against 29·01 in 1902, the district rates ranging between 38·10 in Darrang and 18·22 in Lakhimpur. Darrang was the only district in which the death-rate was higher than the birth-rate.

From all the chief diseases there was a decrease in mortality. Deaths from cholera fell from 12,658 or 2·40 per 1,000 to 8,360 or 1·58. This, however, was the highest rate of all the provinces except Bengal. The diminished mortality was almost exclusively confined to the districts of Cachar and Sylhet in the Surma Valley, but only in the district of Nowgong was the mortality excessive (6·73).

The mortality from small-pox was unusually low, giving a rate of only 0·21 per 1,000 against 1·26 in 1902. The disease was most prevalent in the Cachar and Nowgong districts, and though the former returned the highest ratio in the province, its mortality was much below that of the previous year. Sixty per cent. of the small-pox deaths occurred among children under ten years of age.

The death-rate from fevers, including *kala azar*, was 14·22 per 1,000 against 14·72 in the preceding year, the mortality being highest in the Goalpara and Darrang districts. From *kala azar* 5,033 deaths were recorded, of which Darrang district contributed more than a half (2,657). There has been a steady decrease in the mortality under this heading since 1897, in which year there were 18,597 deaths from the disease.

From dysentery and diarrhœa the death-rate fell to 1·99 from 2·13 in 1902. Of the individual districts the mortality was highest in Lakhimpur and Sibsagar, in which the tea garden population bears a higher proportion to the total than in other districts of the Assam Valley.

Plague visited the province during the year for the first time and caused 28 deaths, the outbreak lasting from the 16th of May to the 3rd of July. Energetic

measures were taken for dealing with the outbreak and there was no opposition on the part of the people.

In the Madras Presidency the year 1903, like its predecessor, was one of abundant rainfall and reduced food prices, and was marked by a further increase in the birth-rate from 28·2 per 1,000 in the previous year to 31·2; the district rates ranged from 39·2 in Chingleput to 23·3 in Madura. The mortality was higher by 94,226, the total number of registered deaths being 826,663, or 22·2 per 1,000 against 20·2 in 1902. In the districts the death-rates ranged from 37·9 in Madras to 14·6 in Ganjam. Thirteen of the 22 districts registered a death-rate in excess of the Presidency rate. Madras.

The number of deaths recorded as due to cholera was 27,393, giving a ratio of 0·7 per 1,000 of population, against 29,769 or 0·8 in the preceding year. Three districts were free from the disease and in the remainder the mortality ranged from 6,157 or 2·2 in Malabar to one death in Bellary. The Government invited the attention of municipalities to the significant fact that in six municipal towns which had a protected water-supply the rate of mortality during the five years ending 1903 was lower by 66 per cent. than during the quinquennium preceding the introduction of the water-supply.

The death-rate from small-pox fell from 0·7 to 0·4 per 1,000 of population. The mortality was highest in the districts of North Arcot (1·1), Bellary (0·8), South Arcot (0·8), and Cuddapah (0·7). The municipalities were remarkably free from the disease; with a population of nearly two and a half millions, their death-rate was only 0·1 per 1,000, a fact which "goes to show that, in spite of possible frequent chances of importation, the influence of protection afforded by vaccination is demonstrable," vaccination being compulsory in all the municipalities. Over 74 per cent. of the small-pox deaths occurred among children under ten years of age.

Deaths ascribed to fever rose from 277,689 or 7·7 per 1,000 to 314,926 or 8·4, a much lower rate than that recorded in any other province excepting Burma. The Presidency rate was exceeded in 12 of the 22 districts, and the rates of these ranged from 15·8 to 8·6 per 1,000. With the view of exterminating malaria by the conjoint use of mosquito larvæ destruction, administration of quinine to human beings, and minor engineering works, the Madras Government has directed that funds should be allotted by local bodies for experiments in six carefully selected areas. "The officer selected for the duty," the Sanitary Commissioner remarks, "will work under this office and will have attached to him an intelligent engineering subordinate. There are here, therefore, the elements for a thoroughly honest trial of modern methods of dealing with malaria."

Dysentery and diarrhœa accounted for 12,756 more deaths than in the previous year, and the death-rate rose from 1·01 to 1·3, a rate which was exceeded in nine districts, the highest being 5·3 in Madras.

The number of deaths registered under plague was more than in the previous year by 2,496, the total being 13,291, representing a mortality of 0·4 per 1,000, which is not a high rate compared with the rates recorded by other provinces. The Sanitary Commissioner notices that during the year 1902–3 a sum of about £27,000 was expended by local fund boards and municipalities under plague charges. "So far as it is possible to gauge facts," he remarks, "it would seem that in restraining the advance of plague throughout the Presidency, the money demanded is well spent, and that trade and lives are husbanded."

The vital statistics of Bombay Presidency for the year 1903 disclose two notable features—a large and widespread increase in plague mortality and a large decrease in the birth-rate. The registered births numbered 576,949, or 54,444 less than in the previous year, and the birth-rate fell from 34·16 to 31·22. Among the districts, Ahmednagar registered the highest rate of 43·30, followed by Khandesh, 40·64, and Nasik, 40·16. As usual the lowest rate was recorded in the Sind district of Thar and Parkar (13·25). The mortality was the highest on record except that of the famine year 1900, the deaths numbering 811,525 or 43·91 per 1,000 against 721,462 or 39·04 in 1902. In nearly all the districts the death-rates were abnormally high, Belgaum and Dharwar, where plague was most severe, recording rates of over 70 per 1,000, and in nine other districts the rates ranged from 65·99 to 45·14. Bombay.

There was again comparatively little cholera in the Presidency during the year, only 1,825 deaths being recorded, which is the lowest mortality from the disease since the year 1886. The disease was practically confined to four districts in Sind, where 1,752 deaths occurred.

From small-pox there were only 2,732 deaths, and of these Bombay City contributed 1,460. In none of the other districts was the mortality high. Nearly 70 per cent. of the deaths occurred amongst children under ten years of age.

Deaths from fever were fewer by 11,141, the number having fallen from 270,845 or 14·66 per 1,000 of population in 1902 to 259,704 or 14·05. Of the districts Ahmedabad recorded the highest fever mortality (31·19); in 12 other districts the death-rates ranged from 24·83 to 14·16.

The deaths ascribed to dysentery and diarrhœa, which were so numerous during the famine years, notably in 1900, when the mortality was 218,243 or 11·59 per 1,000, fell to 55,443 or 3·0 in 1903.

The deaths from plague reached 281;269 or 15·22 per 1,000, an excess of 96,517 on the mortality of the previous year, and by far the largest number recorded in any province during the year. Nearly a third of the deaths (92,043) occurred in the two districts of Belgaum and Dharwar. Only two of the 25 districts of the Presidency were entirely free from the disease.

IV.—JAILS.

Sickness and mortality in 1903.

The health statistics of the jails of British India for 1903 show a further satisfactory improvement in the health of the prisoners. On the whole there was considerably less sickness, and the death-rate fell from 22·5 per 1,000 of average strength in the previous year to 19·5, which is the lowest rate on record. To this result all the provinces contributed except Madras and Burma, the decrease in mortality being most marked in Coorg, the Punjab, the United Provinces and the Central Provinces. The improvement is the more satisfactory "when it is remembered that the conditions of life, economic and hygienic, to which the majority of the free population have of recent years been subjected have been far from favourable, and that the main causes of sickness within the jails have remained unaltered, and have diminished only slightly and recently in the extent of their incidence." There were 57 deaths from cholera against 24 in 1902, and all other diseases which usually assume an epidemic form showed a diminution. Although plague was so widespread and fatal during the year there were only 23 deaths from the disease in the jails.

The following statement shows the sickness and mortality among all classes of prisoners in the jails and subsidiary jails of the various provinces for 1903 as compared with the previous year :—

Provinces.	1903.			1902.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Daily Sick.	Deaths.	Admissions.	Daily Sick.	Deaths.
Bengal	1,053	38	23·5	1,041	39	25·4
United Provinces of Agra and Oudh.	701	34	15·5	734	35	20·4
Punjab	939	30	19·2	1,137	35	25·0
North-West Frontier Province...	1,117	33	15·6	1,038	32	28·0
Burma	474	21	17·1	537	25	15·9
Central Provinces (including Berar).	816	27	18·2	930	29	23·5

Bombay	529	22	25·8	682	28	28·2
India	755	29	19·5	793	32	22·5

Bengal.

The health of the jail population of Bengal during the year was generally good, and the death-rate among all classes of prisoners (23·5 per 1,000) was lower than in any of the previous ten years except 1898 and 1899. The jail death-rate was considerably below that of the whole population (33·4), which, as stated in last year's report, is satisfactory "considering that a large proportion of the jail population must always be drawn from those classes whose vitality is considerably below the normal standard." In four jails there were no deaths and the death-rates of the central jails, with three exceptions, were very low. The Barisal jail, however, was unhealthier even than in former years, and returned the high death-rate of 90·6 per 1,000. Vigorous steps have been taken to improve the drainage of this jail, to enlarge the site, to increase the accommodation of the building, and otherwise improve its sanitation. There were 24 cases of cholera among the prisoners 15 of which were fatal. There was a further diminution in prevalence of and mortality from dysentery, and one of the most satisfactory

features of the year is that 15 jails had no deaths from the disease. Next to dysentery, tubercle of the lungs, &c., and pneumonia were the most fatal diseases. In spite of the prevalence of plague in many districts the disease attacked only four jails, viz., Bankipore, Arrah, Chapra and Bahr subsidiary jail. They recorded 17 cases, with 12 deaths. In the previous year there were only four fatal cases among the prison population of Bengal.

United Provinces of Agra and Oudh.

The health of the prisoners in the United Provinces of Agra and Oudh was again exceptionally good during the year 1903. Among all classes of prisoners the daily average sick rate per 1,000 of average strength was 34 against 35 in the previous year, and the death-rate 15·5, which was the lowest on record. Of the 56 jails in the provinces there were no deaths in seven, and in 12 out of 32 in which the mortality was higher than the provincial average, the death-rate did not exceed 20 per 1,000. From all the chief disease causes there was less sickness and mortality than in the previous year. There was very little cholera among the prisoners, only 15 cases and 13 deaths having been recorded, and of these 12 cases and 10 deaths occurred in the Agra Central Prison. The epidemic in this jail was soon checked by the removal of the prisoners from the infected quarters into camp. Of other diseases, dysentery accounted for only 60 deaths against 133 in 1902, tubercle of the lungs, &c., 59 against 92, and pneumonia 51 against 61. The great reductiom in the mortality from dysentery was attributed to the excellent sanitary conditions under which the prisoners live, and to the care which is given to the purity of the jail water and food supplies. In the majority of the jails there is good accommodation for isolating and treating cases of dysentery and tubercle.

Punjab.

The health of the prisoners in the Punjab during 1903 was wonderfully good considering the prevalence of disease outside the jails. The ratio of constantly sick declined from 35 to 30 per 1,000, and, notwithstanding that there was a rise of 5 per 1,000 in the death-rate of the free population, the mortality of the jails decreased from 25·06 to 19·18—"a remarkable testimony to the sanitary condition of the jails, and this is made clearer when it is added that throughout the year the jail population has been practically immune from plague." Out of 30 jails, there were no deaths in three, and in eleven others the death-rate was well below the provincial average. Of the remaining 16 jails, the death-rate was higher than the provincial average in 10. Only eight cases of cholera with two deaths occurred in the jails, and all the other chief causes of sickness and mortality were less prevalent and fatal. In spite of the wide-spread prevalence of plague throughout the province, only one death from the disease occurred among the convict population, the immunity enjoyed by the jails being ascribable to the quarantine precautions taken and to the watchfulness exercised by medical officers.

North-West Frontier Province.

The general health of the prisoners in the North-West Frontier Province during 1903 was again satisfactory. With a small increase in the sick rate the death-rate fell from 28·02 to 15·6, which was 12·74 below that of the free population. Of the 19 who died, only 9 were admitted into jail in good health. Malaria as usual figured largely in the causation of disease, and it was specially prevalent at Dera Ismail Khan, owing to the "excessive summer rainfall and the consequent opportunity for the production of anopheles." There were no admissions to hospital for cholera or other epidemic disease during the year, although the former disease prevailed somewhat severely among the civil population.

Burma.

Among the prison population of Burma the admission and constantly sick rates were the lowest on record, but the death-rate rose from 15·88 per 1,000 in 1902 to 17·07. There were no deaths in five out of the 32 jails and in 14 others the mortality was below the provincial rate. The most unhealthy jail was at Mandalay, which recorded a death-rate of 30·13. Nearly half this mortality was due to dysentery, for which the water-supply was held responsible. This has been remedied by an artesian well, and a good and wholesome supply is now said to be obtained. Cholera accounted for seven deaths against nil in the previous year, and there was increased mortality from pneumonia, dysentery and diarrhœa, enteric fever, and anæmia and debility. On the other hand the admissions for tubercle declined from 113 to 84 and the deaths from 45 to 38. The isolation of these cases and their treatment in the open air received the special attention of the medical officers as heretofore.

Central Provinces and Berar.

The health of the prisoners in the Central Provinces and Berar jails greatly improved during 1903. There was no overcrowding to any considerable extent. There was considerably less sickness and the death-rate fell to 18·16 from 23·55 in 1902. Excepting a nominal increase at Jubbulpore and Akola there was a fall in all other jails in the daily average number sick, accompanied in nearly all jails by a remarkable decrease in the mortality. In ten out of the 25 jails there were no deaths. Malarial fevers were as usual the chief causes of sickness, while bowel diseases furnished the largest mortality, though there were only 15 deaths against 32 in the previous year. From tubercular diseases also the mortality was less. The construction of isolation wards in the three central jails of Nagpur, Jubbulpore and Raipur for the treatment of such cases was undertaken during the year. Although plague was epidemic in 12 headquarter towns, the disease failed to establish itself in any jail in the province. Only three cases occurred in the prisons, and of these one was fatal.

Assam.

Among the prisoners of Assam there was considerably less sickness than in the previous year, and the rate of mortality fell from 29·9 to 28·1. There was a marked decrease in the prevalence of malarial fevers, but an increase in cases of dysentery. The improvement was chiefly due to the exceptional healthiness of Sylhet jail, where the death-rate fell from 31·89 in 1902 to 21·74. In only four of the jails was the average strength over 100, and three of these (Tezpur, Gauhati, and Sylhet) contributed 33 out of the total of 41 deaths. In 14 jails no deaths took place. The mortality was excessively high at Tezpur, amounting to 66·71 per 1,000, of which 39·42 was due to dysentery.

Madras.

The general standard of health was well maintained throughout the year 1903 among the prisoners in the Madras Presidency. The death-rate was 18·1 per 1,000 against 17·8 in the previous year, while the ratio per 1,000 of daily average sick (19·8) was the lowest recorded during the past decade. The slight rise in mortality was due to cholera, which accounted for 11 deaths, seven of which occurred in Berhampur district jail. Of the seven central jails only in Trichinopoly did the mortality exceed 30 per 1,000, and there a death-rate of 31·10 was recorded, and two-thirds of the 23 deaths were persons admitted in bad or indifferent health. The number of admissions to hospitals and of deaths from tubercular diseases again declined. Tuberculous patients are treated separately; measures are taken for the disinfection and destruction of infective excreta; open air treatment is as far as possible enforced, and steps are being taken for the provision of special tubercle wards in the larger jails. There was only one fatal case of plague, and this was reported from the Vellore Central jail, the disease being epidemic in the town during the year.

Bombay.

The health of the prisoners in the Bombay Presidency during the year 1903 showed a general improvement. Overcrowding occurred in 7 out of the 15 jails, and was relieved by transfer, and by the use of tents, temporary sheds, &c. The daily average sick rate was less, and the death-rate fell from 28·2 to 25·8. There were no cases of cholera in any of the jails, and there were fewer admissions into hospital under all the other chief diseases, except pneumonia, a serious epidemic of the disease having occurred in the Sind gang, causing 33 deaths out of a total of 37. Admissions for malarial fever were much fewer. The decline was very noticeable in the Central Prison of Yeraoda, where the cases fell from 468 in 1902 to 66 in 1903, the decline being attributed to the distribution of quinine among the extra-mural gangs. Although plague was widely prevalent in the Presidency during the year, there were only 10 cases and 8 deaths from the disease in the jails.

V.—VACCINATION.

General results.

During 1903-04 there were 8,458,464 persons vaccinated in the several provinces of India, being an increase of 25,734 on the number of the previous year. The increase was spread over all the provinces except Bengal, Assam, Madras and Coorg, but in most cases it was limited to primary operations. According to age, 3,746,289 children under one year of age, and 3,234,617 children between the ages of one and six years were successfully vaccinated during the year. The proportion of population protected against small-pox by the year's operations ranged from 48·67 in Coorg to 24·63 in Bombay Presidency. In the vaccination of infants the best results were obtained in the Central Provinces and Berar, the Punjab, Ajmer-Merwara, United Provinces, the North-West Frontier Province.

Statement showing the total number of persons successfully vaccinated during the year 1903–04 :—

Province.	Population among whom Vaccination was carried on.	Number of Persons vaccinated.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Annual estimated Births at 40 per 1,000 of Population successfully vaccinated.

Bengal.

The results of vaccination work in the province of Bengal during the year 1903–4 show a decrease of 33,334 operations on the number for the previous year, and a fall in the proportion of persons successfully vaccinated from 37·21 per 1,000 to 35·62. The decrease, however, was entirely under re-vaccinations, due to the less prevalence of small-pox as compared with the previous year, and the consequent smaller number of re-vaccinations done in connection with the stamping out of small-pox epidemics. But the Local Government is of opinion that the Vaccination Department as at present constituted was unable to cope with the disease, and proposals for re-organising it and increasing the superior staff so as to secure adequate supervision were under consideration. Out of the 49 districts in the province, including the Tributary States of Orissa and Chota Nagpur, there was an increase of vaccinations in 28 and a decrease in 21. Of the total 2,634,563 primary vaccinations 212,537 were performed with calf lymph, 415,310 with lanoline lymph, and 2,006,716 by the arm to arm process, the ratio per cent. of success under each of these methods being 98·83, 97·01 and 98·35 respectively.

In Calcutta the vaccination returns showed a further decline, the total number of persons vaccinated (15,907) being 1,627 less than the number in the previous year (17,534). The Department was again remodelled towards the end of the year, and the change yielded improved results during the last quarter.

United Provinces of Agra and Oudh.

In spite of the continued increase of plague in the United Provinces of Agra and Oudh during the year 1903–4 the number of persons vaccinated rose to 1,667,104, an increase of 1,851 on the figures of 1902–3. There was an increase of 1,856 in the number of successful primary vaccinations. Of the 49 districts 28 recorded increases, the most conspicuous being Cawnpore and Sitapur with increases of 4,010 and 3,831 respectively. The percentage of successful primary cases in which the results were known was practically the same as last year, viz., 97·83 against 97·90. Bovine lymph was very little used, only 23,993 operations being performed with it, with a percentage of success of 97·77. The Vaccination Act is in force in all municipalities and cantonments, but the rules are said to be enforced with a varying degree of energy in different places.

Punjab.

There was an increase of 17,561 in the number of vaccinations performed in the Punjab during 1903–4, but it was entirely confined to primary operations as re-vaccinations showed a decrease of 4,017. Fifteen out of the 27 districts of the province recorded an increase and 12 a decrease of work. Of the 581,221 successful primary vaccinations, over 81 per cent. were infants under one year of age. The Vaccination Act was not extended to any new town during the year. Proposals were, however, under consideration for extending it to the towns of Rewari, Jalalpur and Mianwali. In the majority of the towns in which the Act is in force satisfactory work was done during the year. In certain towns no vaccination work was done on account of the severe prevalence of plague.

North-West Frontier Province.

Good progress was made in vaccination work in the North-West Frontier Province during 1903–4, the total number of operations being 99,176 or 8,883 more than the previous year's total. Of these 94,262 were primary cases with a percentage of success of 91·52. The increase was due to an extension of vaccination work in Chitral where on account of small-pox being epidemic, 28,353 vaccinations were performed. Of the total successful primary vaccinations, nearly 48 per cent. were infants under one year of age, and the number of persons successfully vaccinated per 1,000 of population was 43·10, against 39·85 in the previous year. Both animal and preserved vaseline lymph were used during the year, the former showing in primary cases a percentage of success of 93·14, and the latter of 79·86. Out of the ten municipal towns in the province, the Vaccination Act is in force only in three, viz., Dera Ismail Khan, Bannu and Kohat.

Burma.

The total number of vaccinations performed in Burma rose from 381,773 to 412,564 in 1903–4. The increase was pretty generally distributed except in the Mandalay division, in which there was a falling of in every district save Katha, and in the Chin Hills. Primary vaccinations rose from 355,013 to 385,102, but the percentage of success was lower than in the previous year, being 84·98 against 86·93. In municipalities where the Vaccination Act is in force 86·93 per cent. of the available infants were protected during the year, while in the province as a whole only 19 per cent. of the births estimated at 40 per 1,000 of the population were successfully vaccinated. But vaccination in Burma has much to contend against owing to the strong prejudice in favour of inoculation "and since personal infection is the governing factor in the spread of the disease, small-pox must always be more or less prevalent so long as inoculation continues, and epidemic exacerbations will occur periodically according to the epidemic constitution of the year."

Central Provinces and Berar.

The control of the Berar Vaccination Department was transferred to the Administrative Medical Officer, Central Provinces, at the close of the year under notice and the statistics of Berar are accordingly included in those of the Central Provinces. The aggregate number of vaccinations reached 646,305, the percentage of success in primary operations being 98·52 and in re-vaccinations 74·32. Compared with the previous year there was an increase of 41,190 operations mainly contributed by the Central Provinces as all the Berar districts except Akola showed a considerable decrease, which was in a great measure due to the epidemic of plague. During the year no new town either in Berar or in the Central Provinces came under the operation of the Vaccination Act, and even in the municipalities where the Act was already in force, vaccination work was somewhat back-

ward, only 17,769 children under one year of age being vaccinated out of an available total of 21,422.

Assam. The results of vaccination work in Assam during 1903–4 show a decrease of 25,319 operations as compared with the previous year. The decrease occurred in eight of the 13 districts. Inoculation is still carried on, and the question of taking measures to prohibit it in certain districts where it prevailed was under consideration. The percentage of successful primary operations was 97·87 or almost the same as in the previous year. Vaccination of children under one year of age decreased, only 26·29 per cent. of the number available being protected against 28·48 per cent. in the previous year. In towns where the Vaccination Act is in force a mean of nearly 70 per cent. of the children available for vaccination were protected, the figures varying between 85·71 in the Union of Golaghat and 39·41 in Gauhati. The amount and quality of the work done at the Animal Vaccine Depôt at Shillong was not so satisfactory and complaints were received regarding certain early supplies.

Madras. The total number of vaccinations performed in the Madras Presidency during 1903–4 was 1,309,985, a falling off of 22,224 cases as compared with the preceding year. The decrease was mainly in local fund areas, and was accounted for by deficient and irregular supply of lymph, absence of small-pox, and prevalence of plague and absence of vaccinators. The percentage of success remained stationary being 90·8 against 90·7 in the preceding year. A satisfactory feature of the year's work is an increase of 41,505 in the number of children under one year of age successfully vaccinated, but the total number represented only 27½ per cent. of the estimated births. Vaccination is compulsory in all the municipalities, and a ratio of 75 per cent. and upwards was attained by 41 towns against 38 in the preceding year. Of the various lymphs in use during the year calf to arm vaccination yielded the highest percentage of successful cases ; viz., 98·5, followed by 96·9 with animal lymph in tubes and plates.

Bombay. In the Bombay Presidency the number of vaccinations performed rose in the year under notice to 587,933, or 9,048 more than in 1902–3, a result which is very satisfactory "considering that it was achieved in spite of a severe plague epidemic and numerous changes in the supervising staff." Out of the total number of primary vaccinations 510,726 or 92·65 per cent. were successful. Exclusive of Native States and Aden, which are not under the supervision of the Vaccination Department, 363,038 infants, or 79·99 per cent. of the available infants were successfully vaccinated. Human lymph continues to be used in the vast majority of cases, and the percentage of success following its use is everywhere high. In the Southern Registration District vaccination with preserved lymph (lanoline paste) has met with great success and measures have been taken to facilitate its more extended use. A scheme for the establishment of a central depôt for the preparation of preserved lymph for the whole Presidency and Sind at Belgaum is stated to be under consideration.

No inoculation was reported to have been practised anywhere during the year, and no instances were reported of any disease having been communicated through vaccination.

I.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

The following comparative statement shows the number of hospitals and dispensaries under official control open in the several provinces of India during 1903 and the previous year, and the number of patients under treatment :—

Provinces, &c.		Number of Institutions.	Number of In-door Patients.	Number of Out-door Patients.	Total Number of Patients.
Bengal	1903	597	50,673	4,360,682	4,411,355

Bengal.

The number of dispensaries at work in Bengal outside Calcutta during 1903 was 23 in excess of that of the previous year, and the total number of patients treated rose by nearly a quarter of a million. But although there was a general increase in the attendance the number of in-patients decreased by 1,564 as compared with the figures of the previous year, due partly to an improvement in the public health. A satisfactory feature in the returns is the increased popularity of the dispensaries among female patients who numbered 41,251 more than in 1902. The attendance of children also increased by 55,293. There was an increase of patients under all the chief diseases except malarial fever, from which there was a decrease of 28,205 cases. The death-rate amongst the in-patients was 96·1 per 1,000, against 104·7 in 1902. The popularity of these institutions is further shown in the continuous increase in the number of operations which rose from 171,647 to 184,420 ; of these 213 were fatal. Among the more important operations there were 2,772 cases of cataract.

The following statement shows the number of in-door and out-door patients treated in the several hospitals and dispensaries in Calcutta and Howrah during 1903 and the previous year :—

NAME OF INSTITUTION.	1903.				1902.			
	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.	In-door Patients.	Out-door Patients.	Total Number of Patients.	Died per 1,000 of In-door Patients treated.

GRAND TOTAL	27,178	260,910	288,088	134 9	29,063	260,769	289,832	142·9

At the various medical institutions in Calcutta there was a decrease of 1,744 in the number of patients which was due to an improvement in the public health of the city. The decrease was confined to in-patients and was shared in by 9 out of the 12 institutions which accommodate this class of patients. The improvement of the public health is shown in the marked decrease in the number of malarial fever cases from 49,504 to 44,962. Diseases of the zymotic group were also less frequent, cases of cholera, small-pox, plague, enteric fever and cerebro-spinal fever having all diminished. Among the in-patients there were 3,669 deaths, giving a ratio of 134·9 against 142·9 in 1902. The total number of operations performed during the year was 29,473, against 28,385 in 1902, and deaths resulted in 225 cases against 200.

United Provinces of Agra and Oudh.

There was an increase of seven in the number of dispensaries at work in the United Provinces of Agra and Oudh during 1903, and a decrease of 125,674 in the number of patients, the falling off being due to the supply of medicine in larger quantities at one visit to out-patients, thereby lessening the daily attendance. Among the in-patients there were 2,849 deaths against 2,420, and the death-rate rose from 43·8 per 1,000 to 53·3. Of the diseases for which the patients were treated there were 2,493 cases of cholera, as compared with 1,069 in the previous year, and cases of malarial fever fell by 45,467. The number of surgical operations was 185,087, and of these 158,492 were successful and 453 were fatal. Among the operations, 5,172 were for cataract.

Punjab.

There was an increase of one in the number of hospitals and dispensaries at work in the Punjab during the year 1903, the total being 252. The attendance of both in-patients and out-patients exhibits an increase of 296,200 over that of the previous year, and the fact "that this marked rise occurred during a year in which plague was more severe than in any previous year seems to dispose effectually of the theory put forward in last year's Report that the prevalence of plague may account for diminished attendance owing to apprehension on the part of the people regarding the treatment they will be made to undergo." Of the total 3,315,326 patients under treatment during the year, 54,686 were in-patients, of whom 2,332, or 42·8 per 1,000, died, against a mortality of 2,385, or 47·5, in 1902. Of the total number of patients the largest increase occurred among those treated for malarial fevers (increase,

122,486 cases) and diseases of the eye and ear ailments (increase, 43,728 and 25,750 cases respectively). In the number of surgical operations performed (162,396) there was an increase of 9,348, which the Lieutenant-Governor considers an excellent record of work. Of the total operations 157,997 resulted in cure and 269 were fatal. There were 5,326 operations for cataract, and of these 4,841 were successful.

North-West Frontier Province.

The popularity of the dispensaries in the North-West Frontier Province was well maintained during the year 1903. Returns were received from 39 dispensaries, and at these 547,360 patients were treated, being an increase of 25,601 on the attendance in the previous year. Of the 7,787 in-patients, 5,925 were cured and 348 died. Cholera was responsible for 189 cases against only one in 1902. There was a marked increase in cases of malarial fever, Dera Ismail Khan being the chief contributor, the cases having risen by 9,811 over the figure for the previous year. The total number of operations performed was 23,026, or 1,236 more than in 1902. The results showed 22,553 cases as cured and 54 deaths.

Burma.

A total of 134 hospitals and dispensaries under Government supervision were working in Burma during 1903 or five more than in the previous year. At these 979,194 patients were treated, being an increase of 53,780 over the figures for 1902. Of the 47,934 in-door patients, 77 per cent. were returned as cured, and 2,675 or 56 per 1,000 died, as compared with a mortality of 63 per 1,000 in the previous year. As usual malarial fevers headed the list of diseases for which patients sought treatment, next in order being worms, ulcers, diseases of the eye, and diseases of the digestive system. Cholera was more prevalent, and the cases treated in the hospitals rose from 278 to 674. The number of surgical operations continued to increase, and in 1903 aggregated 23,086. Amongst the patients operated on 22,323 were cured and 89 were fatal.

Central Provinces and Berar.

During the year 1903 there were 153 hospitals and dispensaries at work in the Central Provinces and Berar, and at these 1,560,427 patients were under treatment, against 1,727,512 in the previous year, a decrease of 167,085. This decline in attendance had reference to both in-door and out-door patients, and was mainly due to evacuation of towns on account of plague. "As the epidemic progressed," it is reported, "the towns were practically deserted for considerable periods, the inhabitants were scattered over the neighbouring country, and even if they were eager to attend the hospital, were probably deterred from doing so through fear of approaching the centre of infection." As regards the number of patients treated for different diseases, the most important variation as compared with 1902, was a decrease of 72,323 in the number of fever cases, which was attributable more to the plague scare than to any decline in the prevalence of this disease. The number of surgical operations performed during the year totalled 38,352, and of these 37,585 were cured and 89 were fatal.

Assam.

In the province of Assam there were 127 dispensaries open during 1903, being the same number as in the previous year. In spite of the healthiness of the year there was a further large increase of 70,320 patients treated, which is an indication that the popularity of the dispensaries is increasing. The number of in-patients rose from 6,883 to 7,025, and of these 4,418 were cured and 759 died, giving a death-rate of 108·0 per 1,000 against 110·4 in 1902. Of the various diseases for which the patients were treated the largest numbers were under skin diseases and malarial fever. It is a satisfactory feature of the year that cholera cases declined from 2,571 to 1,768. The total number of operations rose from 17,417 to 18,150; but these were mostly of a trivial character, and only 790 were important.

Madras.

In 483 hospitals and dispensaries in the Madras Presidency 4,973,642 patients were under treatment during the year 1903, a decrease of 17,003 on the total of the previous year. The decrease was entirely amongst children, as both amongst men and women there was an increase. Of the 60,382 in-patients more than half were cured and 3,773 or 62·5 per 1,000 died, against a death-rate of 70·2 in 1902. Among the general diseases treated which formed 29·10 per cent. of the whole number the most important were malarial fevers, worms, and rheumatic affections. Cholera cases declined from 5,141 to 3,254. During the year 157,737 operations were performed, a decrease of 6,204 on the number of the previous year. The results show that 149,858 were cured and 402 died. Of the more important operations 1,420 were for cataract.

Bombay. The number of medical institutions in Bombay Presidency rose to 316, an increase of four on the number at work in 1902, but the patients treated decreased by 23,868. The in-patients numbered 50,734, and of these 33,788 were cured and 6,339 died. The most common diseases were as usual malarial fever, but during the year the admissions decreased in number as also did admissions from cholera and bowel complaints. The number of patients admitted into the hospitals and subsequently found to be cases of plague was 1,197, of whom 356 died and the remainder were transferred to plague hospitals. The surgical operations performed during the year numbered 84,558 with a mortality of 490. Of the more important operations 944 were for cataract.

Lunatic Asylums.

Bengal. At the six asylums in Bengal (viz., Bhowanipore, Dullunda, Dacca, Patna, Cuttack, and Berhampore) 1,348 lunatics, including 315 fresh admissions and re-admissions, were under treatment in 1903, being an increase of 95 on the number of the previous year. In the course of the year under notice 197 patients were discharged (130 as cured), and 106 died. Compared with the figures of 1902, the number discharged was more by 73, and the mortality more by 10. At the end of the year there were 1,045 persons still under detention, or 12 more than at the close of 1902. The general health of the lunatics was satisfactory during the year. The number of admissions to hospital rose from 604 to 613; the average daily number of sick fell from 66 to 62; and the death-rate rose from 93·5 to 100·5 per 1,000 of average strength. There were ten cases of cholera against one in 1902. The cause of insanity was traceable only in 46 per cent. of the total number of lunatics, and 183 cases were ascribed to ganja smoking.

United Provinces of Agra and Oudh. The inmates of the four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the United Provinces of Agra and Oudh in 1903 numbered 1,417, including 281 fresh admissions during the year, against 1,391 in 1902. Before the close of the year 200 patients were discharged, of whom 150 were reported as cured, and 67 died, leaving 1,150 under treatment at the end of the year. The cause of insanity was unknown in nearly half (688) the cases under treatment. The general health of the patients was very good in all four asylums, particularly in Lucknow.

Punjab. The Lunatic Asylum at Lahore continued to do useful work. The total number of lunatics in 1903 was 664 (including 161 fresh admissions), against 627 in 1902. At the end of the year the number was reduced to 537 by the discharge of 87 patients, and 40 deaths. The health of the inmates of the asylum was on the whole satisfactory: the daily average sick fell from 45 to 41 and the death-rate from 79·4 per 1,000 of average strength to 76·4. The cause of insanity was unknown in 288 of the cases under treatment. A new Female Lunatic Asylum has been constructed to accommodate nine Europeans and 64 natives.

Burma. The Rangoon Asylum is the only one in the province of Burma, and has accommodation for 416 insanes. During 1902 there were 544 patients in the asylum, including 122 fresh admissions, and the total was reduced at the close of the year to 442 by the discharge of 65 patients for different causes and the death of 37. The health of the asylum was on the whole good during the year. No epidemics prevailed and the average daily sick fell from 33 to 23, and the death-rate from 105·7 per 1,000 of average strength to 86·7. The cause of insanity was unknown in 269 cases.

Central Provinces. In the two asylums of the Central Provinces (Nagpur and Jubbulpore) there were 361 lunatics under treatment during 1903, an increase of 4 on the number in 1902. In the course of the year 33 patients were discharged as cured or otherwise and 22 died, leaving 306 still under treatment at the end of the year. In the Nagpur Asylum the year was not a healthy one especially among the female inmates, owing to a severe outbreak of influenza at the end of March resulting in 31 attacks with 7 deaths. Of the total 22 deaths, Nagpur recorded 14, being in the ratio of 89·7 per 1,000 of average strength against 7 or 45·9 in 1902. At Jubbulpore there were 8 deaths, being in the ratio of 51·9 per 1,000, against 6 or 39·2 in 1902. The cause of insanity was unknown in 152 cases.

There is only one lunatic asylum in the province of Assam, and this is situated in Tezpur. The total number of lunatics under treatment in the asylum during 1903 was 182, or 9 more than in the previous year. Of these, 28 were fresh admissions. At the close of the year the patients in the asylum were reduced to 157, 15 of the total number having been discharged, and 10 having died. The daily average sick was 11 against 10 in the previous year, and the death-rate rose from 56·0 per 1,000 of average strength to 64·3. The increase in sickness was partly due to overcrowding, and in view of the increased numbers of patients in the asylum the construction of a new male ward has been sanctioned. The cause of insanity was unknown in 117 cases. Assam.

At the commencement of 1903 there were 574 patients under treatment in the three lunatic asylums (Madras, Vizagapatam, and Calicut) of the Madras Presidency. During the year 170 fresh cases were admitted, bringing the total population up to 744, or 8 more than the number in the preceding year. In the course of 1903 there were 116 cases of discharge, and of these 102 were cured or improved. The accommodation was ample, and there was no overcrowding in any of the asylums during the year. There was slightly less sickness among the patients than in the previous year. The daily average sick fell from 48 to 47 and the deaths from 45 or 77·6 per 1,000 of average daily strength, to 41 or 69·0. There was no epidemic in any of the three asylums. The cause of insanity was unknown in 338 of the total 744 lunatics under treatment during the year. Madras.

The total population of the seven lunatic asylums of the Bombay Presidency was 1,114, including 317 fresh admissions, against 1,295 in 1902. In the course of the year 266 patients were discharged, 93 of them as cured, and 66 died, leaving 782 under treatment at the close of the year. The health of the inmates remained good and considering the average population of the asylums there has been a marked decrease in the amount of sickness during the last three years. The daily average sick fell from 38 to 34, and the death-rate, per 1,000 of average strength, from 90·0 to 83·0. Of the total of 1,114 lunatics, the cause of insanity was unknown in 511 cases. Bombay.

Medical Schools.

The number of medical schools open in Bengal during 1903–04 was 11, the same as in the previous year. The Medical College, Calcutta, and four of the medical schools are maintained by Government, the rest are unaided. The college consists of two departments, viz., the English department and the military pupil class. The four Government medical schools train pupils as Civil Hospital Assistants, and the six unaided schools follow their own standards for private practice. Bengal.

The students of the Medical College are required to undergo three University examinations during their five years' study, viz., the Preliminary Scientific examination at the end of the second year, the first L.M.S. or the first M.B. examination at the end of the third year, and the second L.M.S. or second M.B. examination at the end of the fifth year. The total strength of the College at the end of the session 1903–04 was 519 (including 16 women), against 555 in the preceding year. As regards the examinations, 206 candidates were successful, or at the rate of 48·4 per cent., as compared with 45·3 per cent. in the previous year. Of the 206 successful candidates, 26 passed the Preliminary Scientific L.M.S. examination, 59 passed the first, and 59 the second L.M.S. examinations; 29 passed the Preliminary Scientific M.B. examination; 12 passed the first and three the second M.B. examinations. In the combined Preliminary Scientific and First L.M.S. examinations there were only seven candidates, but five passed; and 13 passed the combined Scientific and First M.B. examinations.

The average number of students attending the four Government Vernacular Medical Schools at Calcutta, Patna, Dacca and Cuttack was 741. 91 pupils passed the final examination.

The number of pupils attending the Agra Medical School in 1903–04 was 258 (including 54 women), or 14 more than in the preceding year. The results of the examinations were satisfactory, the percentage of successful candidates was 69 in the Civil Class and 56 in the Military Class. The pupils are carefully examined at the end of each year's work, and are not promoted to the next higher class unless they pass the annual examination of their class. United Provinces of Agra and Oudh.

Punjab. The average attendance at the Lahore Medical College and School was more by 13 as compared with that of 1902–03, viz., 542 against 529. Of these 234 were in the College and 308 in the Medical School. The results of the year's examinations show that for the Preliminary Scientific Examination 42 out of 73 candidates passed. In the first L.M.S. and M.B. examinations 20 candidates out of 40 passed, against 25 out of 28 in the previous year, and in the second L.M.S. and M.B. examinations 22 out of 25 passed, against 20 out of 39 ; in all 84 out of 138 or 61·0 per cent. were successful, as compared with 83 out of 122, or 68 per cent. in the previous year. In the School department 84 candidates went up for the final examination for the hospital assistant diploma and 58 passed or 69 per cent., against 60 passes out of 92 candidates in the previous year.

The North India Medical School for Christian women at Ludhiana had 42 students on the rolls at the end of 1903, or seven less than in the previous year ; of these 19 belonged to the Medical class, six to the Compounders' classes, nine to the Nurses' classes and eight to the *dais*.

Madras. The average number of students at the Madras Medical College (including the School Department) during 1903–04 was 324, of whom 32 were women students. Of the 150 students in the College for the various examinations in medicine (including 11 women) 128 candidates entered and 76 passed, against 64 out of 111 in 1902. In the school department the students numbered 174 (including 21 women) and for the final examination for the Apothecary grade 17 candidates appeared and 13 passed, and 97 of the previous year's class of sanitary inspectors appeared for the Government examination in hygiene and 56 passed.

The Hospital Assistant department of the Medical College was at the beginning of the year transferred to Royapuram and constituted into a separate school. This school and the other two medical schools at Vizagapatam and Tanjore had on their rolls 245 pupils, and of these 80 appeared at the final examination of hospital assistants and 59 passed.

Bombay. The attendance at the Grant Medical College, Bombay, rose from 657 in 1902–03 to 677 (including 45 women) in 1903–04. For the first University examination in medicine 178 candidates presented themselves, of whom 121 passed ; and for the second examination in medicine 95 passed out of 197 candidates. For the final examination for the degree of L.M.S there were 122 candidates, and of these 65 passed, two of whom were women.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad continued to work satisfactorily. The average daily attendance was 237.

VII.—SANITATION.

In Calcutta substantial progress was made during the year in ridding the city of many objectionable and insanitary bustees or collections of native huts, resulting in the opening up of many unhealthy areas by the construction of public squares and the making of new roads or widening old ones. The scheme for the drainage of the suburbs was well in hand, and large portions had been completed; but they could not be utilised until other portions had been carried out. The scheme for the surface drainage of the suburbs was under preparation. Satisfactory progress was made with the conversion of the intermittent to a continuous filtered water-supply, the population supplied under the scheme having nearly doubled during the year; in the area under constant supply the average daily consumption during the year was 21·5 gallons a head. The corporation have sanctioned a scheme to increase the daily supply by six million gallons by the erection of new pumps at Pulta. A scheme was also under consideration for improving the unfiltered water-supply by the substitution of larger mains, &c. Bengal.

In many of the other towns of Bengal much good work was done in improving sanitation and water-supply. In the south suburbs of Calcutta the filtered water-supply scheme was completed, and the new scheme for improving the water-supply of Darjeeling was brought into operation. In the towns of Burdwan, Asansol, Manicktolla, Barisal, Gaya and several others, schemes for extending or improving the water-supply were also in progress. Schemes for the improvement of drainage were in course of preparation for several towns.

The Sanitary Board held four meetings during the year, and continued to advise the Government and local bodies on the important sanitary projects. The Board also continued the inquiry into the septic tank system of sewage disposal, and prepared estimates for the construction of septic tank latrines in several municipalities.

In the United Provinces of Agra and Oudh many sanitary improvements in various directions were effected during the year 1903. Large drainage works were in progress at Benares, Cawnpore, Agra, Lucknow, and other towns, and expensive schemes for Fyzabad and Mirzapur were sanctioned. As part of the programme of plague prevention a grant of over £13,000 was made by the Local Government in the spring of the year for the general cleaning up and sanitary improvement of smaller municipalities and towns. A further grant of £4,000 was also made for the improvement of wells in the smaller centres of population. In addition the Government propose to relieve the municipalities from the year 1904 of police charges to the extent of about £23,000 and to make a special grant of about £6,700 for cleaning up certain towns and large villages. On the whole, activity in sanitary matters was the most prominent feature of the municipal administration of the year, and the liberal subsidies given by the Government to the poorer towns enabled them to carry out much useful work. United Provinces of Agra and Oudh.

The Sanitary Board held seven meetings during the year at which they considered and approved projects, amounting to over £84,000, for improving the sanitary condition of municipalities. The estimates show an increase of 16 per cent. on those of the previous year.

In the Punjab good progress was made during the year in the important works which have been undertaken for the improvement of the sanitation of Simla, and in the water-works of Amritsar city. The Lyallpur drainage and water-works were completed, some progress was made with the intra-mural drainage scheme of Delhi city, and improvements to the water-supply were in hand in Lahore, Umballa and Dharmsala. Interesting experiments have been made with septic tanks in Simla, and as the results on the whole have been satisfactory it has been decided to install tanks at once at all the outfalls and to continue experiments with the filters. Special attention was being given to village sanitation, and good progress was made in the matter of protection and clearance of wells. The system of village sanitary notebooks is in force in every district, and is found to be of considerable value. Punjab.

Six meetings of the Sanitary Board were held during the year, when several drainage and water-supply schemes were considered and approved and forwarded to the Local Government for disposal.

North-West Frontier Province.

No large sanitary works were completed in the North-West Frontier Province in 1903, but considerable sums were expended on minor works in the municipal towns, and "these works," it is stated, "may be expected to improve the already excellent sanitary conditions of these towns, which is shown by the freedom from epidemic disease which they enjoy." The expenditure on sanitary works was equal to 20 per cent. on the aggregate income of the municipalities. At the close of the year an extensive drainage scheme was begun for the city of Dera Ismail Khan. In Peshawar city a sum of nearly £1,900 was spent on the water-supply improvements, and on the extension and up-keep of its drainage system ; and in several other places attention was paid to water-supply by the construction of new wells and the cleaning out of old wells and tanks.

Burma.

The municipalities of Burma spent 54 per cent. of their income on sanitary works, and more than half (32 per cent.) of this was expended on works connected with water supply. The Hlawga water-supply scheme at Rangoon which is being carried out to augment the present supply from Victoria Lake, was approaching completion, and the new supply is expected to do much to improve the health of the town. The Mandalay water project has been completed, and the waterworks for Moulmein and Prome were in course of completion. Some progress was also made with the Prome drainage project. A successful experiment in the disposal of refuse was made by the construction of a septic tank at Maymyo, and the engineer's interesting report on the working of the installation has been commended to the attention of all municipal bodies in Burma. On rural sanitation a sum of nearly £11,000 was expended during the year by District Funds.

The Sanitary Board met on two occasions in the course of the year, when sanitary projects referred by Civil Officers and municipalities were considered, among them being proposals for a surface drainage scheme and for an underground sewage system for Moulmein town.

Central Provinces and Berar.

No new sanitary work of any great importance was undertaken in the Central Provinces and Berar during 1903. In connection with the Nagpur waterworks a sum of £3,800 was expended in laying a duplicate rising main, and in providing a new pump. In Bhandara and Burhanpur the water-systems were extended, and that at Harda improved, and in Khandwa and Burhanpur drainage surveys were completed. In the municipalities a number of minor sanitary works were carried out during the year chiefly in connection with improvement of the water supply and the construction and repair of drains. As regards rural sanitation, good work was done under conservancy and clearing of village sites. No new villages were brought under the provisions of the Village Sanitation Act during the year. A special grant of £1,670 was made by the Local Government for the improvement of the water supply in the villages and a scheme for its expenditure was approved. The Village Sanitation Act is not in force in any Berar villages.

Meetings of the Sanitary Board were held during the year at the head-quarters of all districts in the Central Provinces with the exception of Seoni and Nagpur. Steps have been taken to maintain in each district council's office a record of desirable works of village sanitary improvement, as well as a register of all wells constructed in connection with the sanitary scheme, with a view to their being periodically inspected and kept in good repair. In Berar the meetings of the Sanitary Board have hitherto been held at district head-quarters during the rains. There is nothing in the nature of a district sanitary scheme. Proposals for sanitary improvements have usually been made by the Sanitary Commissioner, and the cost debited to district funds. Apparently no local aid has ever been sought. It is stated that it will probably be found desirable to alter the constitution of the Board and its procedure.

Assam.

No important sanitary work was undertaken in Assam during the year, and there was no provincial scheme of any importance under consideration. Excluding four small towns which have no separate income of their own, the municipalities spent over 73 per cent. of their total income on sanitary works. In rural areas the sanitary improvements effected were chiefly in the direction of providing a purer water supply by the construction and repair of wells and tanks, and in improving village sites. The system of village sanitary inspection books was kept up in certain villages, but in several cases continued neglect was shown with regard to the submission of the books, and in others they were reported as of no practical value.

No meetings of the Sanitary Board were held during the year. The Sanitary Commissioner was consulted unofficially on all matters relating to sanitation, and during

the touring season he inspected the sanitary condition of all the headquarter stations and of nearly all the sub-divisional towns, and in some placed on record criticisms for information and guidance.

In Madras City progress was made with the new drainage scheme and a number of minor sanitary improvements were carried out, consisting chiefly in the closing of unused wells, &c. The quantity of water supplied to the city from the Red Hill Lake was nearly 2½ per cent. greater than in the previous year, and the level of the lake was about half an inch higher at the close of the year than at the beginning. Madras.

As regards sanitation in the other municipalities of Madras Presidency, the Vizagapatam and Cocanada water-works were completed and open for use, and those at Coonoor, Guntur and Dindigul were in course of construction. No drainage schemes of importance were executed during the year, but the scheme for the drainage of a portion of Madura town was completed and submitted for the approval of Government. Experimental filters were constructed for the disposal of the sewage from the King Institute of Preventive Medicine at Guindy. Schemes for improving the water supply of several towns were under consideration, as well as schemes of drainage for others. In addition plans and estimates relating to 101 minor sanitary works were checked and scrutinized by the Sanitary Engineer, who also prepared a type design for wooden staging for drawing water from tanks.

The Sanitary Board did good work during the year. They scrutinized the plans and estimates relating to 149 sanitary works of the total estimated cost of £118,000, amongst the more important being the drainage of Madura and Ootacamund, the water supplies of Vellore, Yercaud and Kodaikanal, improvement of the sanitation of Ootacamund, improvements to the market at Coonoor and a general market at Calicut.

In Bombay City progress was made with the special drainage scheme. The Fergusson Road and Chinchpokli sectional sewerage works and the Parel sectional sewerage works were completed during the year. The drainage works in connexion with the scheme for subsoil and surface drainage were commenced; and other works of a minor character were in progress. Drainage connections were carried out for 711 houses, and the work of constructing public latrines and urinals in various parts of the towns was pushed on. The lakes and reservoirs which supply the city with water were maintained in good condition. The rainfall was plentiful, and the Tansa and Tulsi lakes were fully replenished. In the course of the year 329 new water connections were made and 179 were cut off, leaving a total at the end of the year of 20,833. Bombay.

With the exception of Ahmedabad and Karachi none of the other municipalities of the Presidency were in a condition to undertake costly works, their available funds being required for minor works which had been postponed owing to the expenditure and loss of revenue due to plague and famine. At Ahmedabad the extension of the drainage made good progress, and the municipality raised a further loan of £20,000, for continuing the work. For the extension of the Karachi drainage, estimated to cost £78,000, the municipality applied for a loan, and the Sanitary Commissioner visited the town and reported on the scheme. The Village Sanitation Act was in force in 265 villages against 294 in the previous year, the decrease being due to the abolition of 37 non-working committees in the Poona District. The Act provides for the establishment of a sanitary committee or a sanitary board, consisting of members chosen by the collector of the district or by the local Government to supervise sanitary matters. Sanitary inspection books have been introduced into 3,598 villages, and in 51 per cent. of these the books have been written up by officers of the Sanitary Department. In Broach the books have been introduced throughout the district.

The Sanitary Board met only once during the year when a number of minor questions were discussed, and a recommendation was made that two surveyors should be appointed to work under the Sanitary Engineer for the purpose of preparing small projects for municipalities.

LIBRARY OF THE BOMBAY BRANCH OF THE ROYAL ASIATIC SOCIETY

Meteorology of the Year.

Summary of the meteorological phenomena of the year.—The following report on the meteorology of India has been kindly furnished by the Meteorological Department of the Government of India.

During the first half of January the weather over India was generally quiet and fine, though some rain occurred over the south, centre, and north-west, between the 5th and the 10th. About the 20th the weather changed and a series of storms passed through Persia and Baluchistan into Northern India, occasioning rain on the plains, snow on the hills and very unsteady temperatures. These conditions were not, however, maintained and the weather was even finer and quieter in February than in January and the month was marked by a considerable, persistent and general excess of pressure, great dryness of the air, absence of cloud and deficiency of rainfall. In January the weather was cooler than usual over north-west and north-east India and hotter than the average elsewhere, while in February the mean temperature was lower than the normal except in the extreme north-west and extreme north-east. The rainfall of January was deficient except over south India, the west coast and north-east India, and that of February was deficient except along the west coast, over Bengal and on the Burma coast. In March the weather was more disturbed than usual in the north-west of India and adjacent regions, and the total rainfall of the month was from twice to six times the normal amount over Baluchistan, the North-West Frontier Province, the Punjab, Kashmir, Western Rajputana and the hill districts of the United Provinces. In Burma, Bengal and Assam the month's rainfall was normal or in slight excess, while elsewhere the dry weather which had characterised the two preceding months still held. The air was drier and the cloud amount less than usual except in parts of north-west India, but the mean temperature, owing probably to the unsettled weather in the north-west was lower than the average in all divisions, but particularly so in the Indus valley and north-west Rajputana.

During the two hot weather months of April and May the rainfall was much lighter and the disturbances fewer than usual over Burma and north-east India, but in the Gangetic Plain and Chota Nagpur in April and in north-west India and the Peninsula in May the rainfall exceeded the normal. In consequence, while the mean temperature was in marked excess over north-east India and Burma, it was generally below the normal elsewhere. The highest temperatures recorded during May were 120° at Jacobabad on the 31st and 114·8° at Ahmedabad on the 21st.

The monsoon rains set in along the west coast between the 11th and the 16th of June, and over Bengal on the 16th, but the monsoon was light on both sides of India throughout that month. Monsoon rainfall did not extend properly inland and the whole of the area served by the Arabian Sea branch of the monsoon current reported more or less deficient rain. In north-east India the rainfall was generally excessive, but this result was largely due to the very showery weather which prevailed there during the first half of the month. Both the cloud amount and the humidity were generally low. As a result of these conditions the temperature on the mean of the month was normal or in slight defect over inland Burma, Assam and Bengal and Orissa, but was in considerable excess elsewhere, most so over the central parts of the country, where the heat was very excessive from the 8th to the

25th. The temperature rose to 123·5° at Jacobabad on the 11th, to 119° at Montgomery on the 13th, to 118·2° at Dera Ismail Khan on the 13th and 14th, to 117·8° at Bikaner on the 15th, and to 116·4° at Jhansi on the 10th. During the first eleven days of July scattered, though in places heavy, rain fell over the south of the Peninsula, the Burma Coast and north-east India, but none was received over northern India or the north of the Central Provinces. In consequence, very excessive temperatures prevailed over West Bengal, the Gangetic Plain, and the adjacent districts of the Central Provinces, Central India, Rajputana and the Punjab, where on some days the maximum temperature was between 15° and 18° higher, and the mean temperature between 14° and 18° higher, than usual. The highest maxima reported were 117·6° at Jacobabad on the 9th and 10th, 117·7° at Dera Ismail Khan on the 10th and 117·5° at Peshawar and Sialkot, also on the 10th. On the 12th July a change occurred, and rain extended, accompanied with a fall of temperature, but the rainfall was not steady, and a partial break in the rains prevailed over northern India from the 24th to the end of the month. The temperature on the mean of the month was excessive over northern India and Burma —more particularly over the Gangetic Plain—while it was normal or in slight defect over the Peninsula, the North-West Frontier Province and the North-West Himalayas. The cloud amount and the relative humidity were both below the normal except over the Peninsula, where both were in excess. The rainfall of the month was about normal on the Burma Coast, short of the normal over inland Burma and northern India, except the extreme north-west, and in excess over the Peninsula.

During August the Arabian Sea monsoon was on the whole weak and the rainfall normal or slightly below the normal over the west and centre of the Peninsula and north-west India. On the other hand the Bay monsoon was strong and a succession of storms passed from the Bay inland and the month's rainfall was heavier than usual over the east of the Peninsula and Central and north-east India. The mean temperature of the month was nearly normal except in Sind where the heat was somewhat excessive. The highest maximum temperature recorded was 113·8° at Montgomery on the 23rd. Both humidity and cloud were, on the whole, less than the average.

Conditions were unchanged during September. The monsoon was, on the whole, weaker than usual over the Arabian Sea, but the rains continued in Upper India till between the 12th and the 19th. The Bay monsoon was, on the contrary, active, and a series of small storms was formed and occasioned rain over north-east India. The general rainfall of the whole country was in excess of the normal. The departures of the mean temperature from the normal were generally small and unimportant. The air on the mean of the month was damper than usual and the mean cloud amount in excess of the average.

During October and November the weather was generally quiet and fine over the extreme north-west of India, but was disturbed elsewhere. Excessive rain fell in the former month over the greater part of northern and central India, while over the Peninsula the usual rains from the north-east monsoon partially failed. In November the area of fine weather extended and covered all parts of the country except Assam, inland Burma and south India, where the rainfall was excessive. The mean temperature varied irregularly from the normal in these two months.

The first three weeks of December were fine over northern India, but disturbed and showery over the south of the Peninsula and the Burma Coast. About the 24th the weather changed in the north-west and between the 25th and the 28th general rain fell over the plains of north-west India and heavy snow on the hills. The temperature on the mean of the month was lower than usual in most places, but especially so over the Western Desert, the west of the United Provinces, part of Central India, Orissa and inland Burma. Both cloud and humidity were below the normal over nearly the whole country.

The temperature conditions were fairly normal on the mean of the year. Mean temperature was in slight excess over the Burma Coast and the Bay Islands and in slight defect over the Indus Valley and north-west Rajputana.

Pressure on the mean of the year slightly exceeded the normal over the Indian area except along the west coast and over south India, where it was in very slight defect. For the whole Indian area the departure from the normal was + ·005 inch, and, as in the previous year, the departures from the normal were very large both in February and in October.

The relative humidity, on the mean of the year, was below the normal over the whole of India, with the exception of south India, where it was in slight excess. The air was damper than usual in September and October and drier generally in the remaining months.

The cloud amount was generally above the normal in January, May, September and October, but varied irregularly from the average in the other months of the year. On the mean of the year it was in slight excess over Bengal and Orissa, the Gangetic Plain and Chota Nagpur, the Deccan and south India and below the normal elsewhere.

The rainfall of the whole year was in slight to moderate defect over inland Burma, Bengal and Orissa, the Gangetic Plain and Chota Nagpur and the Upper Sub-Himalayas, but was normal or in excess in all the remaining divisions. On the mean of the whole area for the year there was an excess of 0·30 inch. The rainfall was generally in excess in August, September and October, and was irregularly distributed in the remaining months of the year.

European Troops.

Sickness and mortality in 1903.—The average strength of the European troops, excluding officers, which was 60,540 in 1902, rose to 70,445 during 1903; the number of new arrivals in the country was 24,840 and 15,126 in the corresponding trooping seasons. The statement below will show at a glance the general position as regards the sickness and mortality in 1903 as compared with the previous year and the antecedent quinquennium, and this will be seen to be, in all respects, favourable. The ratio of admissions to hospital is the lowest on record, and one must go back to 1877 to find a lower constantly-sick-rate; the death-rate has been lower on seven occasions, but it is so far satisfactory in the light of the facts that 51 per cent. of the strength was under 25 years of age, and that 28 per cent. had less than one year's service in India.

Years.	Average Strength.	Ratio per 1,000 of Strength.				
		Admissions into Hospital.	Constantly Sick.	Deaths.	Invaliding.	Total Loss.
1897–1901... ...	65,044	1,285	81	16·69	35	52
1902	60,540	1,078	66	14·68	37	52
1903	70,445	1,033	63	13·05	29	42

The chief causes of sickness were venereal diseases and ague, which accounted for 23·9 and 23·5 per cent., respectively, of the total number of admissions from all causes. The decrease in sickness is to be attributed chiefly to lower admission-rates from malarial fevers, venereal diseases, respiratory diseases excluding tubercle, dysentery and hepatic affections, while the most notable increase was observed in those from simple continued and enteric fevers, influenza, cholera and heatstroke.

The chief causes of mortality were, as usual, enteric fever and abscess of the liver, the former yielding 32 per cent. and the latter 9·9 per cent. of the total number of deaths, but there was a slight fall in the rates from both these diseases as compared with 1902. And this is the case with nearly all the other death causes, the only notable exceptions being small-pox and cholera.

The chief causes of invaliding were, in order, ague, debility, secondary syphilis and *Bilharzia hæmatobia*, which together accounted for more than one-third of the

total, but there was a remarkable decrease in the numbers sent home on account of secondary syphilis and debility; 134 of the 158 cases of invaliding for *Bilharzia* are definitely noted as having been contracted in South Africa, and probably all owe the same origin. If this new and exceptional source of loss be deducted from the total number invalided, the rate per 1,000 falls to 27·4, the lowest figure since 1895.

Among the troops composing the Delhi manœuvres and Durbar force the chief causes of sickness were venereal diseases and ague, and of mortality, enteric fever and pneumonia, which together accounted for 66 per cent. of the total of 15 deaths which occurred up to the end of February when demobilization took place. From the Aden Column Field Force, with an average strength of 832, there were reported altogether 719 admissions and 23 deaths, giving ratios of 864 and 27·64 per 1,000 respectively; ague and dysentery were accountable for 47 per cent. and 8 per cent. of the sickness, and dysentery and enteric fever together for just over half the mortality.

Commands and Stations.—Comparing the year with its predecessor, and taking all factors of sickness and mortality into account, all the four commands as hitherto considered, exhibit a better standard of health, save Madras (including Burma) which shows no change. Henceforth the statistics of Burma will be discussed separately, and in this, the first year of the new arrangement, it shows, with Madras, the highest sick-rates, the lowest being returned from Bengal and the Punjab. On the other hand, Bengal (15·46) and Burma (13) have the highest death-rates, and Madras (9·24) the lowest, all being somewhat above the respective rates for 1902, and the decrease in the combined death-rate for India is due to the falls in the Punjab and Bombay ratios of 1·5 per 1,000 and 7·26 per 1,000 respectively; the latter and more remarkable result is due to a decrease under nearly every chief cause of death. Among stations with a strength of over 100, the highest death-rates were recorded at Naini Tal (42·25), Delhi (40·27), Dinapore (39·08), Murree (39·06), Mian Mir (36·77), and Nasirabad (35·66), the chief causes of excessive mortality being enteric fever, abscess of the liver, cholera and dysentery, one or more predominating in the different places. Turning to the largest stations, those with a strength of over 1,000, of which in 1903 there were 20 with an aggregate strength of 34,278, it is found that the combined admission-rate (all causes) was 998 and the death-rate 12·28 per 1,000, both below the means for India. Among these cantonments the highest death-rates were reported from Peshawar (22·15), Meerut (19·65), Ranikhet (19·06), Umballa (18·95), and Sialkot (18·41), enteric fever and cholera being the chief causes of the excess. In nine of these stations the death-rates were under 10 per 1,000.

Geographical Groups.—The geographical groups which, on a consideration of the sickness and mortality rates in combination, may be said to have been most unhealthy in 1903, were Burma Coast (I), Central India (VIII), and Bengal-Orissa (IV), while at the other end of the scale stand the Hill Stations (XII *a*), Western Coast (X), and Deccan (IX). The death-rates in the former were 15·38, 20·01, and 15·17 respectively, in the latter, 8·87, 8·37, and 8·97, or if the actuals of the two sets be combined, the rates stand at 18·48, and 8·88 per 1,000 respectively, *i.e.*, as just over 2 to 1; the respective combined admission-rates are as about $1\frac{1}{2}$ to 1. The clearest view of the causes of this contrast may be obtained by a glance at the table on page 40, but it may be noted here, briefly, that malarial fevers, bowel complaints, venereal diseases and hepatic affections were more prevalent in the former groups, and that the greater mortality therein was chiefly due to enteric fever, respiratory diseases, dysentery and hepatic abscess. Some idea of the occasional fluctuation of the mortality rates in the same group from year to year is obtained when it is noted that in Bengal-Orissa (IV.) the death-rate fell from 24·32 in 1902 to 15·17 in 1903, mostly due to the decrease in deaths from hepatic abscess; again, in the Western Coast (X), the fall was from 21·34 to 8·37 in the year under review, owing chiefly to diminished loss from enteric fever, respiratory diseases and hepatic abscess.

To sum up the main results for 1903: if the sickness, mortality and invaliding rates had been the same as those of the previous year, there would have been 3,162 more men admitted to hospital, 220 more constantly sick, 115 more deaths, and 561 more men invalided. These considerations should enhance the significance of

Influenza.—Influenza was widely prevalent, cases occurring in all the commands and in all but one of the geographical groups (VII). The admission-rate for India, which was 8·9 per 1,000 in 1901, and 1·8 in 1902, rose again to 3·1, the incidence being greatest on the Bengal (5·5) and Madras (3·3) commands, while the Bengal-Orissa group (IV) was affected to the extent of 23 per 1,000 of its strength. Southern India (XI) and the Hill Stations (XII *a*) were the only other groups

with rates above the mean. There were altogether 215 admissions, with no fatality, reported from 29 stations, Fort William, Barrackpore, Chaubattia, and Ranikhet, with from 20 to 22 cases each, reporting 40 per cent. of the total. It is said that an epidemic wave swept over Calcutta and the district in August and September, and this accounts for the cases at the two first-named cantonments; as regards the two Hill Stations, the source of infection was not traced, but is attributed in Chaubattia to importation, the disease, however, appearing exclusively in April and May.

Cholera.—Cholera was more generally prevalent among the civil native population in 1903 than in the previous year, and this is reflected in the army returns. There were only three cases among the European troops in 1902, but the number rose to 81 with 57 deaths in the year under review; these were reported from 16 stations in which all the commands shared, but the only considerable outbreaks were in Ranikhet (24 cases with 16 deaths), Meean Meer (13 and 11), Sialkot (10 and 6), Umballa (8 and 6), and Fort William (8 and 5); seven other stations reported only one case each. In nearly all accounts it is noted that the sources of infection were abundant in that the disease was prevalent at the time among natives in the cantonments, bazaars, neighbouring towns, or villages. In the case of Ranikhet, it was concluded that a spring which had been taken into use to supplement the deficient water-supply, but which was not thoroughly protected from surface pollution, had become contaminated, probably by natives. The outbreak began three days after heavy rain, and did not cease until this source of supply was closed, although the water was boiled before issue; bacteriological examination failed to detect the *vibrio*. At Sialkot the incidence of the disease and the general course of events appeared to implicate the regimental dairy milk, though no direct source of infection of this was traced. The Fort William cases are definitely attributed to the drinking of impure water by men on the march just outside Calcutta; and at Umballa, as all connexion between the cases appeared to be excluded and no general source of infection could be traced, it was considered that each case arose independently by fortuitous contact with natives.

Small-pox.—Both the admission and death-rates on account of small-pox rose in 1903 as compared with 1902; there were 68 cases and 8 deaths recorded against 23 and 4 respectively in the previous year. Eighteen stations contributed to this result, the largest numbers being recorded in Lucknow (22 cases with 4 deaths), Peshawar (7 and 2), Agra and Bareilly 4 cases each without a fatality, and the Delhi Durbar force in camp, 5 non-fatal cases; on the other hand, eight stations furnished only one case each. It will be seen that the Punjab and Bengal Commands were chiefly affected; it was in these areas that the disease was most prevalent among the native population, and medical officers record the fact that sources of infection prevailed in and around cantonments. Of the Peshawar cases all had been vaccinated in infancy or subsequently, and 16 of the 22 had been re-vaccinated, mostly within the last five years. The disease was of the modified type in 14, and confluent in 8 cases; one man had had a previous attack in 1896 and recovered again. The cases occurring in Agra and Bareilly had all, it is said, been vaccinated and re-vaccinated.

Ague, remittent fever, simple continued fever, Malta fever.—Intermittent fever was the cause of just over 23 per cent. of the total admissions, which is about the same proportion as in 1902; it was more prevalent in all the commands, save Bengal and Madras, but the aggregate admission and death-rates fell from 247 and 0·5 per 1,000, respectively, to 243 and 0·34 per 1,000 in 1903. The separation of the Burma district from Madras Command brings out the contrast between these areas in regard to the prevalence of malarial fevers; but the high rates in Burma have been returned on a comparatively small strength, about one-fourth of which has been concentrated at one unhealthy station, Mandalay, where more than half the admissions for intermittent fever have occurred in recent years.

Excluding Burma, the Punjab Command usually takes the first and worst place, while Madras is at the other end of the list, and these positions are maintained once again in 1903, with rates of 312 and 135 per 1,000 respectively. As regards geographical groups the greatest prevalence was, in order, in Central India (VIII),

Indus Valley and Frontier (VII.), and Upper Sub-Himalaya (VI.), and the lowest in Southern India (XI.) and the Hill Stations (XII. *a*), the admission-rates ranging from 441 in Group VIII. to 95·4 in XI. Excluding the Hill Stations and comparing 1903 with the previous year, there was a decrease in the amount of the disease in 40 cantonments, an increase in 32, the Punjab Command stations alone showing an exception to the general rule of decrease, and it is among these and some in the Bombay Command that the highest rates are recorded, *e.g.*, Fort Lahore, Amritsar, Mian Mir, Aden, Nasirabad, Peshawar, and Ferozepore, all above 500 per 1,000. A reference to pages 35 and 36 will show that there was, generally speaking, a defect and an irregularity of the monsoon rains in June and July, some excess in August and September with a later persistence into October than is usual, and medical officers refer to one or other of these conditions as promoting the prevalence of fevers. The high rate at Aden is due to the men infected when on service with the Field Force operating in the Hinterland. It is quite probable, further, that just as a storm in the English Channel will often involve recourse to treatment in the London hospitals of malarial patients returning from the tropics, so the high range of temperature with cold nights in the autumn of Upper India may be expected to cause relapses in old cases of infection, or lower the resistance to fresh attacks.

Prophylactic measures.—The subject of the prophylaxis of malarial fevers is discussed as a whole in General Remarks, page 122, and it is unnecessary to give here a detailed summary of the medical transactions in this respect. There can be no doubt that the efforts put forth during the past year have been far more general, more complete, more consistently and energetically maintained and better organised than heretofore. At the same time signs are not wanting that in many respects the work has yet to be developed in its range and in completeness, before we can hope for measurable results. To this end other factors should contribute, and chief among them is a more scientific nosology based upon the recognition of the specific exciting *causæ* of the different forms of malarial fevers, and this will, of course, entail the systematic use of the microscope in diagnosis; and, further, the success of practical preventive measures will largely depend on the interest taken in, and the encouragement given to, them by non-medical officers of corps. A few of the medical officers refer to the fact that lectures on and demonstrations of the simple facts on which preventive measures are based were given to the men with encouraging results, and this is a procedure that might be more generally adopted. In some cantonments "mosquito-brigades" were organized, and from a considerable minority of stations it is reported that the *anopheles* or its larval form was discovered at one or more periods of the year, but the variety is rarely stated and there is little information as to the relative seasonal prevalence of the *anopheles* found and the forms of fever in evidence. In at least 13 stations it is said that a careful search failed to discover *anopheles* of any kind, but most of these stations are in the hills and the fevers met with there were ascribed for the most part to importation. There are not a few references to the fact or probability of importation by men arriving from some endemic centre, and this tends to vitiate, to some extent, the deductions based on the returns as to the exact geographical distribution of the disease. For the rest, it may be noted that the microscope was used as an aid to diagnosis in a minority only of the stations, and the results are not always stated. The practical measures adopted were, for the most part, the improvement of surface drainage, the removal of standing collections of water in and around cantonments, the use of kerosine oil as a larvicide; in brief, the measures advocated by Ross. In a few cases, mention is made of the use of mosquito-curtains for malarial patients in hospital and for the men in barracks; in other instances the provision of nets has had to encounter the opposition of the men on account of the alleged defective perflation of air their use involves. The administration of quinine as a prophylactic was very generally adopted during the height of the fever season and care was taken, as a rule, to ensure its ingestion by the men under proper supervision. But it can scarcely be said that this measure has had a thoroughly systematic trial; the dose, the interval between doses, the method and the period of administration have varied in almost every instance and very few medical officers have committed themselves to an opinion of its value. A discussion of the subject of preventive measures in cantonments will be found under General Remarks, page 122.

It is quite possible that one may see in the reduction of the reported prevalence of so-called remittent fever in 1903, one result of a more careful effort to differentiate

this anomalous class on etiological grounds; when specific parasites are demonstrated in the blood more regard may be paid to their etiological significance than to the vagaries of the temperature chart and of the clinical symptoms. At any rate the fact stands that while the admission and death rates for India for the quinquennium 1896-1900 were 19 and ·34 per 1,000, and for 1902, 6·7 and ·20, they fell to 4 and ·14 per 1,000 respectively in the year under review. The difference in the last two years depends on the decrease in the Bengal and Punjab Commands where the rates have usually been highest, and with an increase in influenza and dengue, and no marked diminution as a whole in intermittent fever, the fact is at least worthy of notice. Medical officers, as a rule, include any remarks they may have to offer on this subject in the discussion of malarial fevers; the term remittent fever is generally held to include cases that run a somewhat anomalous and severer course and which are not subsequently found to develop a recognisable specific entity apart from malaria. The season of maximum prevalence for India as a whole is generally fairly identical for intermittent and remittent fevers, but in the different commands and geographical groups there are considerable divergencies in the monthly incidence of the two classes. When autopsies are made the chief care is to exclude enteric fever, which may have been overlooked during life. The Punjab Command as a whole usually occupies the highest place on the list and this is the case in 1903; but the stations with the highest rates were Port Blair, where the strength is very small, Barrackpore, Nasirabad, and Maymyo.

The suggestion made above as to a cause of the diminution in the returns of remittent fever, may appear less plausible when it is noted that there has been an increase in the simple continued fever rate as compared with 1902, viz., from 14 to 18·5 per 1,000, but for this again the rate for the quinquennium ending 1900 was 35·4. This disease is remarkable for its large fluctuations in the returns, but they do not exhibit any regular relation, direct or inverse, with the remittent fever rates. The maximum seasonal prevalence is usually coincident with the height of the hot weather or with the onset of the first rain of the monsoon, the latter a time of considerable range and sudden falls in temperature; attacks are commonly attributed to chills and exposure to sun and heat, and may be largely due to lack of adequate physiological adjustment, or to malarial relapses. The Madras and Bombay Command rates have been highest in recent years, but in 1903 the Bengal and Punjab Commands stand first and show a considerable rise over the rates of the previous year. As regards geographical groups the incidence in 1903 was markedly highest on Gangetic Plain and Chutia Nagpur (V) and Indus Valley and Frontier (VII). As regards stations, by far the largest number of cases was treated at Mooltan and Lucknow, but the question of the etiology is not discussed by the medical officers concerned.

There were nine cases recorded as due to Malta fever, without a fatality, against eight admissions with one death in 1902; the reporting stations were Allahabad (4), Rawal Pindi (2), Khyragalli, Peshawar and Quetta one case each. None of the patients appear to have been stationed in any Mediterranean port, and the diagnosis, which was suggested on somewhat slender clinical grounds, was held to be established by the serum test, and, as regards this, particulars of the origin and history of the micrococcus employed are wanting, and in only three cases is the dilution mentioned, viz., 1 in 80. It is noteworthy also that of the five stations from which cases were reported in the previous year, only one, Rawal Pindi, appears in this year's list. Further, it does not appear that any attempt has yet been made in India to isolate the specific micrococcus. One can only conclude that, so far, the evidence is not sufficiently weighty for a positive diagnosis, more especially in the light of the recent observations of Konrich in Berlin. Working with cultures obtained from Wright (Netley) and Eyre (Guy's Hospital) he obtained complete agglutination in one hour, with the serum of hospital patients in different dilutions up to as high as 1 : 500; some of these patients had been treated with tuberculin, but the serum of others, who had not been so treated, reacted as markedly, and none of them had been exposed to any source of infection of Malta fever. The results further showed the greatest variations in the reactions of different races of the microbe to the same "normal" serum, which would agglutinate one race at 1:20 and others in different dilutions up to 1:500. Again, Captain Cornwall, I.M.S., has tested the reaction of the serum of certain healthy individuals as well as of some patients suffering from long-continued, ill-defined forms of fever with a culture of the micrococcus sent to him at Madras from the Pasteur Institute,

Kasauli. Among the persons in good health he found five out of six Hindus whose serum gave a "partial" reaction at 1 : 20, and in two of these cases there was also a partial reaction at 1 : 100; the serum of three healthy Europeans gave no reaction. Among the patients, the symptoms of none of whom suggested Malta fever, there were some whose serum reacted completely in dilutions of 1 : 80, and in three cases there was a partial reaction at 1 : 400. It would, therefore, appear that a "positive" reaction in dilution of 1 : 80 cannot be held to be pathognomonic of Malta fever, and that the serum of patients suffering from other diseases may give misleading indications.

Enteric Fever.—The literature in which are set forth the results of the work accomplished during the past year towards the elucidation of the problems of the etiology, diagnosis and prevention of enteric fever, is, as usual, enormous in amount and unusually extensive in its range. If it cannot be said to include any single contribution which alters fundamentally our conception of the disease, it, nevertheless, leaves the impression of a definite advance in the co-ordination of independent efforts under the influence of a clearer and more consistent view of the whole subject from the epidemiological side. Much of the constantly accumulating sum of knowledge has been confirmed by the test of fresh experience, by the wider application of more exact methods of research and by the recognition of the limits of the value of some of these methods. While the effective etiological factor has lost something of its specific unity owing to the recognition of the pathogenicity of organisms of the paratyphoid class, and while the uses and limitations of the Widal reaction in clinical diagnosis have been more strictly defined, the results have been rather to demonstrate the improvement in technique and in reliability of the methods at our disposal than to confuse the main practical issues. There is, indeed, satisfactory evidence of a definite advance in our capacity to control the disease, provided always that the resources in skill and laboratory equipment are available, and the gain may be said to consist in this, that we now realize what, previously, we knew, namely, that enteric fever is preventible by direct measures of attack and not merely as the result of general measures of sanitation.

To this end several factors have contributed, but no one more than the recognition of the prime importance of the human host as the source of infection. The danger to the community of the patient exhibiting all the typical signs of the disease has not always been duly recognised, and still less, or not at all, that arising from unrecognised cases presenting an aberrant clinical picture, or from light and ambulant cases, from convalescents and from individuals who may harbour and excrete the bacillus while giving no evidence of impaired health. And it is chiefly to Koch that we owe it that our eyes have been opened to the facts in these respects, while he and his followers have demonstrated the practical application of the measures thereby indicated. A full account of Koch's views and methods for the suppression of enteric fever in the endemic form in rural areas was given in this report for last year, and it will only be necessary here to note in its place the more recent evidence, in the course of a brief review of the more important contributions of other workers on the various aspects of the whole subject. It is perhaps not unnecessary to affirm that the problem is after all one, though indeed it has many sides, and that danger may lie in a too exclusive view of any one etiological factor. There has been some tendency to understand Koch to deny, or at least to underrate greatly, the *rôle* of drinking-water in infection, but this is scarcely justified. His view rather appears to be, that while water can and does convey the infection, the viability of the bacillus in water, and as a saprophyte generally, has been over-rated, and that the old exclusive water-borne theory has led to concentration of effort in a direction which has, on the whole, not been justified by results: and while he emphasises the necessity of all measures of conservancy in regard to water and removal of excreta, he would alter the chief point of attack when an outbreak occurs and in the suppression of the disease in an endemic form.

A considerable body of influential testimony is accumulating in favour of this standpoint. It is evident in the remarks made by several authorities in the discussion at the Epidemiological Society, of the paper by Dr. Reineke on the epidemiology of cholera and enteric fever in Hamburg and its suburbs, and still more clearly and concisely in the conclusions in which Pistor, in an address to the same society, sums up the lessons of the course and distribution of the disease in Prussia during the decade 1892-1901. Briefly it comes to this, that the *bacillus typhosus* has a much

shorter existence outside the body than has been commonly supposed, that it does not multiply in the soil, but is transferred from one person to another by means of water, milk, vegetables, or other food articles recently contaminated by the excreta of affected individuals, and also by direct contact; epidemics are, as a rule, due to infection of common water and milk supplies; mild unrecognised cases play a most important part in maintaining a chain of infection through successive sporadic cases, while over-crowding and general neglect of sanitation favour its propagation and extension.

Koch and Pistor alike arrive at this position, as the result of the study of the disease for the most part outside the chief urban centres, but very similar testimony is forthcoming from the great European capitals. Dr. Newman, M.O.H., Finsbury, sets forth the evidence for a large and typical London borough with undeniable force, and Doenitz, from the experience of Berlin, shows how manifold are the indirect sources and the vehicles of infection in a densely crowded city; and consequently, while the suppression of an outbreak on Koch's principles would encounter greater difficulties than in a circumscribed rural area, the measures based thereon are the more necessary to prevent extension from each focus of infection, *i.e.*, by suppression of infection at its source. With regard to the materials at our disposal for a judgment of the methods employed and the results obtained on these lines, we have the most interesting and detailed account given by Von Drigalski of the operations in Saarbruck, where a bacteriological institute was established from which, as a centre, a small laboratory and staff was mobilized for work in any specially affected locality of the area of the campaign; similar arrangements were made in Treves, Metz, Strasburg and Landau. With these resources, it was possible to make a thorough survey of the locality, the essential point of departure being the discovery of all cases of infection, whether in the obviously sick, in convalescents or in the apparently healthy; it remained to carry out measures of isolation and disinfection, preferably in a hospital, until repeated bacteriological observations had justified belief in the absence of infection. The author discusses the means at disposal for the detection of cases, and while endorsing the value of the Widal reaction, affirms that its true function is to serve as an auxiliary and confirmation of the clinical and epidemiological indications. It tells us nothing of the state of infectivity, and so of the public danger of a case, and moreover, as clinical signs frequently fail or mislead, the main resource must be the systematic bacterioscopic examination of the blood and excreta of the sick and of those in contact with them. Details are given of the methods employed and particularly of the selective culture medium first introduced by the author and Conradi, to which reference has been made in this report for 1901, and which it would appear, from this and other independent testimony, has fairly established its claim as a speedy and reliable process, which may be said to hold the field, at present, among its many rivals (see below). The author is by no means concerned to deny the *rôle* of drinking-water in spreading infection, and gives details of an outbreak in which both water and contact-infection operated in mutual dependence; and here again, suppression was achieved by attacking the sources of infection in man after closing the implicated water-supply. Finally, as regards the phenomena of so-called "Typhoid houses," where infection persists, the facts, when closely analysed, are to be explained less on an assumption of the viability of the bacillus in the soil, and outside the body, though the bad hygienic conditions common to such houses may lend colour to that hypothesis, than by a chain of infection maintained from man to man. And this is supported by the facts of the almost universal distribution of the bacillus in the organs and blood of the sick—a septicæmia—which involves its presence in most of the secretions and excretions, and with this the well-established evidence of the infection of healthy contacts, and the important *rôle* of unrecognised cases and convalescents in spreading the disease. This gives but a bare summary of a paper which deserves careful study for the scientific evidence on which the conclusions are based, the practical importance of which should justify this extended reference.

As regards the operations conducted by Professor Frosch in the villages round Treves, we have the independent testimony of Talayrach, which agrees in all essentials with that of Drigalski. Infection by water was excluded on the epidemiological and other evidence, which, on the first examination, seemed to indicate no obvious connexion between the notified cases, but by consultation of the registers of absentees from school, of the sick-clubs and of public health, by testing the blood of each case of illness by the Widal reaction and by the bacteriological examination of their

excreta, a continuous chain of infection was established between the cases. Here, again, it is said that the measures, based on the proof of "contact" infection, were crowned with success. A very similar report is given by Nœtel of an epidemic in Beuthen, in seven localities of which with an aggregate population of 65,000, 927 cases with 84 fatalities occurred in May and July 1900. There were two explosive outbreaks with a month's interval between them, and this suggested forcibly the influence of water or some other common source of infection; but this view had to be abandoned on the evidence, which, with the experience gained during the operations for suppression, was held to substantiate the contact theory, immediate or mediate, by means of contaminated privies and soil. Altogether, the lesson conveyed by these examples is that of the necessity of the training and discipline of our forces, and then of a well-directed attack upon the certain sources of infection, rather than a dissipation of effort in attempts to suppress the bacillus in the environment which are so often fruitless. Finally, some support to this view is afforded from another side in an account by Conradi of an epidemic of dysentery in the environs of Metz, the outbreak presenting all the now familiar phenomena of "contact" infection and necessitating similar measures for its suppression.

Enteric Fever: The Bacilli in Blood, Urine, Fæces, Sputum, &c.—In direct connexion with the human host as the chief source of infection, stands the distribution of the bacillus in the body, and also its means of exit therefrom. Drigalski lays stress on the view of the disease as a "bacteriæmia" rather than a local intestinal affection; post-mortem the bacillus is found in all tissues and organs, and in greater abundance as one ascends from the large intestine and the abdominal organs to the mouth, and thus all secretions and excretions may be expected to contain it in greater or less amount. This gives the key to anomalous and misleading cases which assume the clinical features of other diseases, *e.g.*, bronchopneumonia, bronchitis, influenza, &c. An elaborate paper by Bezançon and Philibert on extra-intestinal forms of Eberthian infection presents a considerable body of evidence on this subject, and there is an increasing number of isolated cases reported in which the bacillus was isolated from the sputum, from the pleuritic effusion and other pathological secretions in which the diagnosis of enteric was not at first entertained. When we came to the presence of the bacilli in the blood, the urine and fæces of persons in one or other of the active stages of the disease we are on familiar ground, and the evidence of the danger of the two chief excreta of convalescents and of light or ambulant cases is also incontrovertible. It is even pointed out by Velich that sudden death in times of epidemic prevalence may be the first obvious sign of the disease, and this is only an indication of many cases which altogether escape recognition and which are a great danger to the community as sources of infection which cannot be traced. Biffi and Galli, in order to ascertain if light cases of enteric ("*typhus levis*") were etiologically one with the typical infection, performed puncture of the spleen on 30 cases with the result that the fluid obtained was sterile in 2 cases, but in 27 others the true bacillus of Eberth was demonstrated. This outline of the essential facts, which have such an important epidemiological bearing, scarcely needs to be filled in here with a detailed *résumé* of the literally enormous number of accounts of work by observers in nearly all parts of the world, with the object of demonstrating the presence of the bacillus in the blood, the urine and the fæces. Year by year the salient facts have been recorded in the successive issues of this report, and the most recent work merely serves to confirm and extend them. Here it may be noted that in connexion with the ascertained limitations of the Widal reaction (see below) the early bacterioscopic examination of the blood is assuming a more prominent place in clinical diagnosis, and as an example of its value, confirmed by many similar statements, the results of Coleman and Buxton may be cited. They examined the blood of 604 cases, of which 23 were classed as paratyphoid, with positive results in 453 of the whole number; of 85 cases examined in the first week of the disease the results were positive in 79, or 93 per cent.; of 198 in the second week, 151 were positive, or 76 per cent.; of 115 in the third week, 66 were positive, or 56 per cent.; and of 55 in the fourth week, 18 were positive, or 32 per cent. In 10 per cent. of the total positive cases the results were obtained in advance of the Widal reaction. Some other workers report positive results along with the absence of Widal reaction in a considerable proportion of cases. The evidence, as a whole, goes to show that for successful bacillary diagnosis the blood is the best source in the earliest stages,

the urine in the later stages and in convalescence, while the fæces contain the bacilli in largest numbers during the second or third week of the disease, and in relapses. Drigalski affirms that he succeeded in demonstrating the germs in fæces several times as early as the second and third day of the illness, and we must look to the possibility of a still earlier excretion, even in the stage of incubation before the bacilli enter the lymphoid tissue. With these facts and probabilities before us it would be safe to assume for practical purposes that a person attacked by enteric is especially dangerous to others before and after he comes into the physician's hands. In regard to methods, a reference to the best approved culture media for examination of urine and fæces will be made in the next section, and the procedure for obtaining cultures from the blood was noticed in this report for last year.

Enteric Fever: Water, Food, Bacillary Diagnosis.—If we look next to the evidence which tends to substantiate the propagative *rôle* of drinking-water, it is not necessarily to assert any antagonism with the views just enunciated, but to avoid the danger of the partial outlook. The experience of the past year has furnished some instances of water infection, which, both by the authority of the workers and the evidence they supply, leave little to be desired in conclusiveness. A good example may be cited in the report by Professor v. Jaksch and Dr. Rau of the demonstration of enteric bacilli in the water of the River Maldau and in the pipe-water of Prague in the spring of 1904, during an explosive outbreak of the disease which furnished cases spread throughout the city in the course of a few days. The account is noteworthy for the details of the methods employed and for the results which leave no doubt of the addition of one more well-authenticated case to the scanty records of scientifically demonstrated water infection. Specimens of the water in question were, in the first place, treated by the process of Hoffmann and Ficker, which consists, briefly, in transforming the water itself into a nutritive medium by the addition of a solution of nutrose, and then, in the addition of solutions of caffein and of crystal-violet (Höchst) with the object of hindering the growth of *b. coli*, while favouring, or, at any rate, not retarding, that of *b. typhosus*. After a few hours in the incubator, plates of the Drigalski-Conradi medium were inoculated with portions of the water thus prepared, and from colonies which gave the requisite indications, bacilli were obtained to which a complete series of critical tests were applied; these included Pfeiffer's phenomenon and the agglutination (1 in 5,000) of an authentic and independent strain of the enteric bacillus by the serum of a guinea-pig which had received an intravenous injection of an agar culture of the suspected water-bacillus, heated to 60° C. for half an hour. All tests yielded unequivocally positive results, with both river and pipe water, and the text of this research, which is clear and concise, will repay study, not only as the complement to that of Von Drigalski, but for the conspectus afforded of the most recent and approved methods. It appears probable that, in this much-vexed problem of bacillary diagnosis, the processes of Drigalski-Conradi and of Hoffmann-Ficker will establish their value as the most important recent contributions to our resources within their respective spheres. Criticism is not wanting, but they have not hitherto been impugned on essential points and it must always remain true that no process will avail without the requisite skill and judgment in its employment. And, doubtless, finality has not been attained; of the most recent attempts at improvement two fall to be noticed as promising to justify their authors' claims to some extent when used in the appropriate circumstances, viz., the malachite-green-agar of Lentz and Tietz, another selective medium which acts by retarding the growth of *b. coli* while favouring that of the enteric and paratyphoid classes (A and B), and secondly, the fuchsin-agar of Endo which differentiates the colonies of *b. coli* from those of *b. typhosus* by the property of acid production inherent in the former with resultant red colouration, while the latter remain colourless. These new media appear to have a sphere of usefulness in examinations of the stools, possibly as supplements or complements of the Drigalski-Conradi process; simultaneous comparative tests of all three have been carried out by independent observers, with results that confirm their value, but more experience is required for an estimate of their relative advantages.

With this exemplary case of Prague before us, it would be tedious, and scarcely profitable, to give details of half a dozen other more or less well-authenticated cases of water-borne infection, accounts of which have appeared during the past year. One of the most careful and exact pieces of work is that of Conradi, who appears

to have succeeded in demonstrating the bacilli in well water, their identification being established by a study of the morphological and cultural characters, by agglutination with specific serum, by the positive results of the Pfeiffer reaction, by their virulence for animals and by the specific protective action for those of an anti-typhoid serum. The epidemiological facts supported the bacillary diagnosis, and the account is noteworthy for a concise summary of the history of similar work and results. In a paper published three months later the same author gives some astonishing results of his experiments on the viability of *b. typhosus* in water, but this account lacks the precise detail which marked the former one, and by which alone an estimate of its value could be formed. Briefly, he affirms that when portions of a spleen from an enteric case were inserted in pipe water and kept at 37° C., the bacilli were recovered after 542 days; when sterile and distilled water were employed, the bacilli were recovered after 429 days. Control experiments with enteric cultures showed a viability extending to 420 days in pipe and in distilled water and to 30 days in sterile water. He notes a change in the biological properties of the organism, owing to its sojourn in water, as shown by the formation of a pellicle on the surface of broth when transferred to that medium, and to this change he attributes the difficulties encountered by others in demonstrating the bacillus in water. The briefest allusion to two outbreaks of the disease (in Riga and in Kingston, Canada) which were traced to the pollution of river-water may take the form of a reference to the original authorities, and finally, on this subject the reader may consult Professor Lorrain Smith's careful study of the etiology of enteric fever in Belfast, in which fæcal pollution of a catchment area is held, by a process of exclusive reasoning, to be the source of the specific contamination of a portion of the water-supply of the city.

Coming next to the recent accounts of alleged infection by food, such as raw vegetables (water-cress), oysters, mussels and fried fish, there is naturally little or nothing to be affirmed on the basis of bacterioscopic examination of the incriminated articles, and the case for a positive verdict rests almost entirely on circumstantial evidence and on a process of exclusion of other sources of infection. Reference has been made to the views of Pistor for Prussia, 1892-1901, of Doenitz for Berlin and of Newman for London, and the interim Report of the Royal Commission on Sewage Disposal, issued last January, is not only important in regard to the evidence of the extent of the mischief caused by sewage—contaminated shell-fish, but also for its discussion of the vexed question of the bacillary criterion of specifically polluted water. McWeeney's report to the Local Government Board, Ireland, is a valuable contribution to the same subject. The general conclusion of the work and opinions of the best authorities may be stated as follows: " mere numbers of *b. coli* or any other particular micro-organism of sewage cannot be said to have anything approaching an exact value as an indicator of the danger of disease " from shell-fish. Klein " would not reject oysters as polluted with human sewage on account of the purely bacteriological examination " yielding *b. coli*, and he emphasises the paramount necessity of a topographical survey for the formation of a judgment! and here the matter rests, for the present, with the declaration that further research is necessary. There is, however, something more definite in the statement made by the medical officer of the port of London in his report for 1903, that cockles, which had lain in Leigh creek, Essex, to which the effluent from " biological " sewage beds has access, were found by Klein to contain the typhoid bacillus, or at any rate, a bacillus answering to all the tests of the *b. typhosus*. It is significant that an independent local medical authority had previously suggested that cases of enteric within his jurisdiction were probably due to the consumption of cockles from Leigh.

It may be noted here, in connexion with the contamination of food and as having a direct bearing on the previous discussion of contact infection, that Winslow reports having examined, bacteriologically, the hands of 111 persons, chiefly students and professors, and that of this number ten proved to harbour *b. coli;* the hands were immersed in sterile water and portions of this were subsequently cultivated on the ordinary media. With regard to milk, nothing demanding special notice has been reported since Schüder's discussion of the subject and Bruck's experimental work on the artificial infection of milk, butter and cheese, both of which were noticed last year. A small outbreak of enteric at Tregantle Fort, Plymouth, was considered to have arisen from contamination of the milk at a farm, the proprietor of which was the local contractor for the removal of sewage, and he appears to have used the close neighbourhood of the dairy as a dumping ground for fæcal excreta.

Enteric Fever: Clothing, Soil, Dust, Flies.—The medical officer of the Port of London (Report, 1903) gives a detailed account of the conveyance of the disease to the port by infected blankets from the field of war in South Africa, a matter which, in another connexion, received notice in this place last year. The danger of the contamination of boots by foul soil and in foul privies, &c., must also be borne in mind, especially for those who have to clean these articles. Doenitz, from the experience of Berlin, notes the tracing of infection to soiled bedding and clothing.

The risk which children run of infection from their habit of playing on the bare soil and of applying their hands to their mouths has been suggested, notably by Koch and his followers, and those in contact with them may often thus derive the disease.

Those who hold by the theory of dust-borne infection are still deriving their evidence and conclusions chiefly from the experience of the South African war, *e.g.*, Tooth and Caldwell. With regard to the question of the *rôle* of flies as disseminators of the disease, Austen gives a summary of the evidence which has accumulated during the last few years, based chiefly on the experience of recent campaigns, and on experiments which have been noticed in previous issues of this report. He then reviews the characteristics, life-history and general binomics of the commonest latrine-haunting species, noting that one, the "house-fly," is as common in India as in South Africa. As to the practical issues, he says that it is not sufficient to insist upon the necessity of promptly burying all refuse, horse-dung, offal, &c., in which flies may breed, of the disinfection of latrines and the effective use of dry earth therein. What is required is some simple means, adapted to service conditions, of preventing the access of the fly to the latrine for however short a visit, and he suggests the employment on latrine trenches of light metal covers, which should be provided with apertures closed by spring flaps, to be operated by the feet of the users.

Hamilton gives an account of some experiments made with flies caught in infected houses and their surroundings during an epidemic in Chicago in 1902; in five out of 18 cases the results of cultures, on media contaminated by these flies, were successful in the recovery of the *b. typhosus*, and altogether 12 different micro-organisms, mostly of the *coli* group, were isolated.

Enteric Fever: Paratyphoid Fever and the Agglutination Test.—The extended application of biological reactions in diagnosis has led to the attempt to differentiate on the etiological side the large group of cases of the enteric class which on clinical grounds were formerly held to represent one pathological state. Hints to this end were furnished by the so-called light, aberrant and abortive cases of enteric fever, and also by the modifications in the pathological lesions found post-mortem; but it is chiefly owing to the development of the technique of the bloom-serum reaction and of our knowledge of its true value and limitations, as also to improvements in methods of bacillary diagnosis, that we are now able to distinguish between true enteric fever due to the bacillus of Eberth and a class of clinically more or less similar fevers, the effective agents of which belong to a series of floral forms intermediate between *b. typhosus* and *b. coli*. One by one these forms have been isolated and their morphological and biological characters studied comparatively, and endeavours have been made to classify them more or less definitely, if provisionally.

It is impossible to discuss this side of the question in detail in this place, but it may be said that so far the whole series may apparently be included in one or other of the following groups, viz. (*a*) organisms of meat poisoning, the bacilli of Gärtner, Basenau, Fischer, Cotta and others; (*b*) those which give rise to an obscure form of pneumonia in man and to disease in parrots, *b. psittacosis;* (*c*) those apparently non-pathogenic to man, *b. typhi murium* (Löffler); (*d*) the paratyphoid group, represented by several members, with more or less close affinities and at present described by the names of their first observers.

These last present certain minor biological differences among themselves, and in virtue of these they have been provisionally divided into two classes, A and B, the former of which approximates, in most respects, more nearly to *b. typhosus*, and the latter to *b. coli*. In regard to their distribution in the tissues and organs of the infected and in the excreta, they are as abundant and widespread as in the case of true enteric which in these respects they closely simulate, and for their isolation and identification precisely similar methods are in use. As regards the serum reaction for clinical diagnosis, the bacilli isolated may be tested, on the one

hand, with an authentic human or animal paratyphoid serum, and, on the other hand, the serum of a doubtful case should be tested with authentic strains of *b. typhosus* and the different members of the paratyphoid class. The weight of evidence, which is abundant and daily accumulating, goes to show that while paratyphoid serum will often agglutinate *b. typhosus* it always acts upon the paratyphoid bacillus, which is in causal connexion with the attack, in very much higher dilutions, a distinction most marked at the height of the disease. The pathological results of infection are, as a rule, conformable to the clinical effects; that is to say, the picture may frequently stand for an ordinary case of true enteric, but, as a rule, there are modifications due to the absence of one or other typical feature of the latter, *e.g.*, a lack of the classic lesions of the small intestine and mesenteric glands, while the tendency to pneumonic complications, to hæmorrhages and to pyæmic deposits is perhaps more marked.

It is also notable that there is frequently local reaction and ulceration in the upper parts of the large intestine, so that, roughly, one may perhaps distinguish a tendency to a bridging of the interval between the pathological *facies* of enteric and dysentery, the causal agent of which last has certain biological affinities with the whole group under discussion. On the epidemiological side the chief points of interest are the persistence of the bacilli in the excreta of convalescents; the fact, now established on good evidence that some, at least, of the organisms can maintain their viability in water and in milk and meat (and one sub-class, as we have seen, is specially associated with meat poisoning outbreaks), and also the tendency of the disease to appear in relatively small epidemics. Lastly, a good many cases of mixed infection have been described, the paratyphoid organism being found in conjunction with the influenza bacillus, with streptococcus and with true *typhosus*. The best and most reliable example of the last is a case described by Conradi, who affirms that to prove mixed infection it is necessary to demonstrate both organisms, not only in the body of the sick but also in the medium of infection, as he appears to have succeeded in doing.

Beyond the intrinsic practical interest of the subject, for a general discussion of which the reader may refer to papers by Clemens, Kayser, Firth, Fischer and Drigalski, the work here summarized derives a special interest and value from its bearing on the problems of serum agglutination. The discovery of the reaction commonly associated with the name of Widal was hailed at first with extravagant hopes, from which there have since been signs of reaction, owing undoubtedly to lack of precise knowledge of the bio-chemical forces in operation, and to a too exclusive reliance on its indications apart from a consideration of the whole clinical and pathological evidence, and frequently in the absence of supplementary bacterioscopic research. It is on this account that the summary just given of the present position of opinion on the paratyphoid question must be received with a certain reserve, for it is based very largely on the results of a single test, which, in some respects, has proved itself to possess only a relative value for clinical diagnosis. It is not denied by any competent authority that it is certainly a valuable aid to diagnosis, that it is, indeed, indispensable, and it may well prove that as knowledge grows, we may see in its very limitations surer evidence of its true worth. Failure has often been the result of haphazard methods and a lack of appreciation of the obscure differences that mark different strains of the same organism obtained from different sources and kept up under varying conditions in the laboratory; and similar variations of a bio-chemical nature have to be regarded in the reaction of the tissues of the organism which provide the conditions for agglutination. The difficulty in obscure atypical cases is indeed threefold, for to the above we must add that of the personal equation of the observer, and what is essential is a judicious estimation of the reaction in the particular case in question, based on a critical survey of the whole evidence. This is enforced by the fact, which appears to be well established by Jürgens, Brion and Altschüler, and Stern in their studies of agglutination curves during the course of the disease, that maximum agglutination values may be given by the serum with bacilli which were shown to have no etiological relation to the illness, and further, that the specific agglutination value is not invariably above that of the group agglutination, which, indeed, cuts at the root of the *rationale* of the differentiation of paratyphoid and enteric fevers. While this gives pause to our acceptance of many published results and opinions, it does not indicate that we are at the end of our resources; such cases are relatively few, and apart from the effect on the serum reaction of mixed infection which may be in operation, it

is precisely herein that Castellani's procedure (exhaustion of the agglutinins) and Pfeiffer's phenomenon are available and probably conclusive. The conclusion we may draw is that, while in the laboratory we can more or less control the factors in operation, the problem of clinical diagnosis may be complicated by the individuality of the case; no single test or symptom can be relied on, but that of Widal will maintain its great value when its results are read in the light of the whole clinical and pathological syndromata, and beyond this, it will, in the great majority of cases, possess a relative value to the patient, the clinician, the epidemiologist by furnishing signs of specific infection, present or past. In using it, any idea of the indications of specificity from arbitrarily fixed dilutions must be abandoned; in each case the observer must exhaust the limits of the reaction of the serum on different micro-organisms of authentic identity and origin which may enter into possible etiological connexion with the case, and so refer not to "negative" or "positive" results but state the facts.

It would seem, also, that any simplification of the serum test, that does not involve loss in accuracy, would prove more profitable than an ever-increasing complexity of technique, with its tax on the judgment of the observer. And to this end, it would appear, from the unanimous consensus of a large and increasing number of reliable authorities who have used it in comparative tests with the ordinary Widal procedure, that Ficker's so-called "diagnosticum" has established its position. This appears to consist in a suspension of a culture of *b. typhosus*, killed by heat at about 58° C., in 10 per cent. solution of glycerine to which some carbolic acid or formalin is added. Along with the abundant and strong testimony to its delicacy and reliability, often exceeding that of the ordinary test, it is recommended for its simplicity and its availability to the clinician in the absence of laboratory resources, and altogether specially adapted for work in military hospital practice.

Enteric Fever: Preventive Measures.—The preventive measures based on the foregoing considerations have already been indicated, but may be summarized briefly in this place. For an effective and systematic campaign against enteric fever we must take account of every possible mode of transmission and form of the disease, and this is especially the case where, as in India, we are unable to discover and control all sources of infection. While taking this view of the problem, which is indeed the problem of general sanitation, it is obvious that as we stand at present, with the disease actually confronting us, the most effective line of action will be to endeavour to prevent the dissemination of the infection from its sources in the human body, while, as far as possible, guarding against the more general and problematic avenues of infection in the environment. As regards the first object, the guiding principle is the prompt recognition of all cases of infection, whether in the persons of the sick or of convalescents, while, at the same time, the special danger from light, ambulant cases and from apparently healthy contacts is not overlooked. To be effective, this work requires the devotion of skilled bacteriologists with laboratory resources, not only for technical diagnostic purposes, but also for local enquiries into the etiological problems involved, with a view to prevention, an aspect of the case which derives special importance in India from the absence of practitioners in the service of the civil population. With recognition must come prompt isolation of the infected person, and disinfection and proper disposal of all his excreta, and of all objects in contact with him, throughout the course of the infection and until there is reasonable evidence of its termination. Disinfection of the home or place previously occupied by the case is also essential, and it may be necessary to secure this by its evacuation for a definite period. Attendants and others in contact with the case must be instructed in measures of personal disinfection, and previous contacts must be carefully watched for signs of infection. Communication must be cut off with places of common resort, *e.g.*, latrines, refectories, &c., and with other localities, cantonments, &c., as far as those who may reasonably be deemed infected, or possibly infected, are concerned. In the case of a fatal event, the strictest sanitary precautions must be taken for the safe disposal of the corpse. For the rest we must look to the strict supervision and control of the food and water-supplies and to conservancy as regards the prompt and effective disposal of sewage and other refuse. Under the peculiar conditions of the European soldier's life in India, we are not at present justified in hoping that the most effective measures of suppression will result in complete prevention, and there can be no

question of the great value to the individual and to the State of an effective means of prophylaxis by "inoculation," and with this, the promotion of all measures calculated to facilitate the physiological adjustment of the young Briton to the strange and trying conditions of the new environment, during the first year of service therein. It is understood that Dr. Wright's anti-typhoid inoculation process, which has been commended by a Committee of the Royal College of Physicians, is to be further submitted to the examination of a body of experts under the auspices of the Army Council and a definite pronouncement on the various questions involved may shortly be expected. Work on this subject has been reported during the year by Shiga, Wassermann, and Bassenge, and Rimpau, and Wright has given a clear and full account of his methods and results, which affords an admirable *résumé* of the scientific basis of the procedure.

Opinions of Medical Officers.—Turning now to the experience and work in India during 1903, we find that medical officers, who see most of the disease at close quarters, have little definite evidence of a direct kind to offer for the solution of the problems of the particular outbreaks they had to deal with. In no single instance can it be said that the source of infection was conclusively traced, but in their accounts of the local conditions and of the circumstances attending the occurrence and course of the disease there is certainly no lack of evidence of the operation of all the etiological factors we are led to associate therewith. There is the usual reference to the youth of the men and to their special liability during the first period of service in the country, and beyond this, opinion appears to be unequally divided as to the relative importance of the conditions which determine the risk and actual acquirement of infection. The general tendency is still to look to the bazaars, villages, and to the environment beyond cantonment limits as the pre-eminent foci of danger. In default of more direct evidence, it is most commonly assumed that infection was derived from articles of food and drink consumed in, or obtained from, native bazaar dealers, or while travelling to join their regiments, or on the line of march between cantonments. As regards the last contingency, the hill stations afford abundant and indubitable evidence of importation, though it is not always clearly demonstrated that the disease was acquired *en route*, rather than from the cantonment of departure. There can be little doubt, however, that direct importation from one infected cantonment to another is a frequent occurrence and a very real danger. The medical officers of more than forty stations refer to importation as the source of part or the whole of the disease with which they were concerned, sometimes as introduced by new drafts from home, or as carried by the men from the plains to the hills, in which cases, convalescents are sometimes implicated, or reversely, introduced into cantonments in the plains by men returning from hill stations in the autumn, or, lastly, by transfers in the plains. It is impossible to ignore the fact that wherever originally derived, many stations constitute endemic foci, which are a potent source of infection for the inhabitants and for men on first arrival, and of danger by dissemination to other places by the constant movements described. These circumstances lend importance to a growing body of opinion, for which the reports of the last few years are notable, which would point rather to the sources of infection within cantonments; stress is laid, and not unduly, on the defective methods of conservancy that prevail, on the improper structure of latrines and urinals and on the very inadequate methods of removal and disposal of excreta. The careless habits of the men, the plagues of flies and dust which are regularly recurrent phenomena in the majority of stations, and the difficulties experienced in protecting food and water from contamination, all derive their importance from this common source of danger. It is notable that one or other aspect of this view is emphasised in the reports for 1903 on the outbreaks in eleven of the chief endemic centres,* where 54 per cent. of the total number of cases occurred, and this does not include all the minor references to the subject. In the light of the work which has recently been accomplished in connexion with the etiology of the disease, these considerations acquire the greatest force; a too ready acquiescence in an exclusive view of sources of infection from outside must lead to lack of concentration of effort for the reform of insanitary conditions with which the men are in constant and immediate touch. The first step in the application

* In Umballa, Meerut, Lucknow, Nasirabad, Mhow, Poona, Rawal Pindi, Peshawar, Bangalore, Jhansi, and Kamptee.

of the principles, which are established by the facts previously summarised, must be in this direction, as striking at the root of the chain of infection.

For the rest, the records travel over familiar ground; the medical officer, as a rule, has to confess himself at a loss for conclusive evidence of the actual origin and means of infection, and so falls back on an enumeration of possible or probable sources, or, by process of exclusion, arrives at one or other most probable source for the case in question. In at least nine stations the drinking-water was reported to be open to suspicion, or was even condemned as polluted, while in as many other instances, it was declared to be beyond reproach; the practice of boiling before issue is generally maintained, but the methods of storage and distribution do not invariably preclude the risk of contamination, and, indeed, sometimes promote it. The majority of the cases at Quetta were attributed to the drinking of water from unauthorised sources by men when on manœuvres, in camp, or on the march. Attacks were thought to be due to the consumption of milk purchased from the bazaar, in three or four cases only, and the exact evidence available for direct contact infection, as by attendance on patients in hospital, does not account for more than half a dozen. A few officers record their opinion of the danger of clothing and bedding which had been used by patients before admission to hospital and subsequently issued to others, and the provision of steam laundries in connexion with station hospitals is suggested. The proximity of native communities and the constant sources of infection provided by the traffic therewith is constantly referred to, and followers and servants who live in the lines are sometimes condemned, not only as importers of the virus from without, but as providing all the elements of danger in themselves and within the fold. It may be noted, finally, that the serum-test does not appear to be employed as a routine procedure in more than a minority of the stations, but among these are the chief endemic centres of the disease.

Enteric Fever in 1903.—The main facts concerning the extent and distribution of the disease during 1903 may now be summarised briefly. The admission-rate after having risen, with slight fluctuations, to the highest point (36·9 per 1,000) in 1898, fell rapidly and steadily during the next three years to 12·8 in 1901, the lowest point since 1885,* previous to which the completeness of the returns is open to serious doubt. In 1902 the tide returned and the rate of that year, 16·7, has been followed by one of 19·6, which, however, with the exception of the three previous years, is the lowest since 1890. These striking movements and the salient features of the rate-curve can be referred in the main, firstly, to the effects of the Frontier campaign (1897-98) on an army largely composed of men at the most susceptible ages, hence the enormous admission-rate of 1898; and, subsequently, to the marked modification in the human material exposed to risks in India, as the indirect result of the Boer war. From 1890 up to the winter of 1898-99, between 15,000 and 16,000 young men were imported into Indian cantonments every year; then for two years the numbers fell off to about one-fifth and one-third, respectively, of that average, and we see enteric fever at the low ebb. And lastly, with a return of the drafts in the last three years, in greater numbers than ever, the rates rise significantly, if not proportionately. The amount of susceptible *personnel* must always be a chief factor in determining the prevalence of the disease, provided that it is exposed to infection, and the final result will vary with the more or less effective interaction of both these factors. Notwithstanding the rise in the admission-rate, the mortality fell off slightly from 4·29 per 1,000 in 1902 to 4·19 in 1903; the case mortality was lower to the extent that in every 1,000 cases, 43 more men recovered in 1903 than in the previous year.

There were, in all, 1,384 cases reported, with 295 deaths, during 1903, as compared with 1,012 and 260, respectively, in 1902; the average duration of a case was 54·35 days and the average number of men constantly sick was 206·07, so that the total loss of service due to enteric fever alone, in 1903, was 75,216 days.

Enteric Fever in Commands and Geographical Groups.—The disease was more prevalent in all the Commands, those of Bombay and Bengal yielding the highest ratios. As regards the geographical groups, Central India (VIII), Upper Sub-Himalaya (VI), and Gangetic Plain (V) stood at the head of the list, all showing a considerable increase in their rates, as compared with 1902, and, as regards the

* It was 12·7 in 1887.

first two, with the corresponding decennial means. In these three groups, which may be considered to comprise the chief endemic area, there were 16 stations from which rates above 20 per 1,000 were reported, 11 stations with rates above 30, and 7 above 40 per 1,000. On the other hand Bengal Orissa (IV) and Western Coast (X) did not, together, furnish more than 3·3 cases per 1,000 of strength.

Enteric Fever in Stations.—From 29 stations rates of over 20 per 1,000 were returned, as was also the case in 1902, and among these the following may be noted, with their admission-rates per 1,000 :—

In Group VIII.		*In Group VI.*		*In Group V.*	
Nasirabad ...	121·8	Meerut	50·4	Dinapore... ...	42·7
Indore	52·6	Umballa	49·4	Lucknow ...	37·7
Mhow	48·0	Sialkot	32·6	Cawnpore ...	21·3
Neemuch ...	41·0	Delhi	23·5	Fyzabad	20·2
Jhansi	38·7	Rawal Pindi ...	23·0		
Nowgong ...	35·0	Roorkee	21·2		

The list also includes Peshawar (33·8) and Jubbulpore (42·1) lying just beyond the areas broadly indicated, and, in addition, eight hill stations. The special points of interest in connexion with all the more important outbreaks have been summarised in previous paragraphs.

Relation of Enteric Fever to age and length of residence in India.—In 1903, as in previous years, the greatest liability to suffer and die from enteric fever fell upon the age-period, 20 to 25, and upon the first year of Indian service; the extent of this liability may be estimated by the fact that the admissions for men up to 25 years of age, that is, on half the total strength, amounted to nearly 76 per cent. of the total admissions at all ages, and that nearly 74 per cent. of all cases occurred among men during their first two years of Indian service, *i.e.*, on 43 per cent. of the strength. A feature of the returns for the last five years, a period of comparatively diminished prevalence of the disease, is the noticeable tendency to a rise in the admission-rates for the higher age and service periods. For example, while only 0·2 per cent. of the total cases occurred among the men over 35 years of age, who formed 3 per cent. of the strength in the triennium 1896-98, the ratio rose to 0·48 on 4 per cent. of strength in 1899-1901, and further to 0·6 on 4 per cent. of strength in 1903. Again, while in 1896-98 5·4 per cent. of the total admissions were from men with five years' service and upwards, *i.e.*, on 18 per cent. of the strength, the ratio for the following triennium was 14 on 29 per cent. of strength, and for 1903 it was 11·6 on 23 per cent. of strength. That is to say that, comparing the last year with the first period, the incidence on the highest age-periods is nearly two and a half times as high, and that on the highest service periods is nearly twice as high. These results may be due partly to more accurate diagnosis, or, perhaps, to a diminution of the acquired immunity in the older men, owing, possibly, to decreased prevalence of the disease in Great Britain during recent years.

Plague and some other General Diseases.—With plague epidemic among the native civil population in far greater extent and amount than in previous years, it was to be expected that the number of casualties would rise among the troops located in proximity to the native communities affected. In 1901 there were two cases recorded with one death; in 1902, four cases with one death, and in 1903 the numbers were twelve and two respectively; but although the disease prevailed widely among the general public in every Command area, it was only in those of Madras and Bombay that the troops were attacked. Bangalore and Belgaum yielded one case each, one being fatal, and Poona, Ahmednagar, Kirkee, Mhow and Neemuch furnished altogether ten cases, with one death at Mhow, in which the disease took the pneumonic form. At all these places plague prevailed in epidemic form among natives, either in the bazaars or in the neighbouring towns, and in most cases evidence was forthcoming of actual contact with cases. There were altogether 20 admissions with two deaths from measles, the majority occurring at the two hill stations, Chaubuttia and Dagshai. To erysipelas were attributed 69 cases with two fatalities, the Bengal and Punjab Commands being chiefly affected. Out of the 26 admissions and six deaths from beri-beri, nine and three, respectively, were reported from Thayetmyo (Burma), and nine and two, respectively, from Aden.

In the former series, which followed on six cases in the previous year, peripheral neuritis and cardiac dilatation and embarrassment were the main symptoms, and the men who succumbed were "noted as large beer drinkers," but analysis of the beer for arsenic gave negative results. The Aden cases were associated with a larger number of admissions for multiple neuritis which are separately returned, the diagnosis of beri-beri apparently resting on the accompanying symptoms of disordered action of the heart, cardialgia and cyanosis, the men who died sinking suddenly with fatal syncope. The medical officer in charge is unable to throw any light on the cause of the disease. There were altogether 303 cases of dengue, or five in excess of the number in 1902; the disease was confined to three stations in the Madras Command, and to three in the Burma district, Fort St. George (Madras) with 82 cases, one fatal, Rangoon 151 cases, and Thayetmyo with 59 cases being the centres chiefly affected, as was the case, as regards the last two, in the previous year. The disease is said to have prevailed in epidemic form from May to August and to have been generally of a mild and ephemeral type, and as noted in this report for 1902, it was believed to have been imported into Burma by Chinese immigrants from Hong Kong. As regards the Madras cases, which occurred during the first six months of the year, the medical officer mentions the theory of importation from Rangoon, to discard it, in favour of his view of its endemicity in Fort St. George; during the outbreak among the troops many of civil residents in the city, both native and European, also suffered.

Mention has been made of the very considerable loss sustained by the invaliding of 158 men on account of *Bilharzia hæmatobia;* altogether 318 cases, with one death, were reported from 33 stations which are included in all four Commands and the Burma district. As regards 293 cases, it is definitely stated that the men had arrived from service in South Africa, but the reports do not indicate what interval, if any, elapsed between arrival in India and the detection of the disease, save in the instance of Deolali where 126 cases were received from South Africa as convalescents and none of these were invalided during the year. One case, admitted in Mian Mir, is important, as the medical officer attributes the infection to local origin. The man had never served in Africa, which, with Arabia, so far as is known at present, is the chief endemic home of the parasite,* but some three months previously another man of the same regiment, who had served in the Boer campaign, had been transferred to a hill station on account of the disease. No other cases occurred at Mian Mir, and it is said that the two men in question "had not been in contact in any way." However this may be, the future course of events must be watched with solicitude; it does not, however, necessarily follow that with the ova of the parasite scattered in many cantonments, the conditions for its development and propagation are present in India. Previous to 1902, when 51 cases were recorded, all, it is believed, due to importation from South Africa, the returns are blank in respect of the disease. Hatch has recorded several cases which he observed among natives in Bombay, chiefly Muhammadans who had made the pilgrimage to Mecca, and he remarks (1887) that "the disease appears to be more common than formerly," and on the evidence of one case, he suggests that the interval between infection and the onset of active symptoms may be something under eight weeks. Scheube affirms that Indian coolies from Madras and Bombay are not seldom attacked in Cape Colony, and as these emigrants are constantly returning to India they probably disseminate the ova in their home surroundings. Nevertheless, the disease is not, apparently, recognised among the indigenous native population, though it is true that only a small proportion of the sickness occurring outside the urban centres, comes under skilled observation.

Many medical officers took the precaution of incinerating the urine of these cases, a measure which should never be neglected, and should, of course, extend to the alvine dejecta. One case is reported where intestinal hæmorrhage together with a tumour in the rectum led to a suspicion of malignant disease, but the microscope revealed a mass of the ova in a matrix of mucous and fibrous tissue.

Tubercle of the Lungs.—There was no change in the admission-rate on account of tubercle of the lungs for the European army as a whole, and for three successive years it has stood at 3·4 per 1,000, while the corresponding death-rates were ·46, ·59 and ·24 per 1,000 respectively, the last being by far the lowest on record; this is

* Cases have also been observed in Mauritius, Syria, Cyprus, Mesopotamia, Penang; Shanghai; one case in North America and one acquired in the West Indies.—(*Scheube*).

due to a fairly equal diminution in the case mortality in all the Commands, save Madras, where the death-rate is generally lowest. On the record for the quinquennium, the Bengal Command stands out with the highest mortality for both European (·71) and native troops (1·10), and the province of Bengal occupies the same place in the Jail Statistics. But in the last two years, so far as the army is concerned, the Bombay Command has returned admission and death rates which are considerably above the average for the rest of India. This is probably due to the returns from Deolali, where men are received from all parts of India prior to their embarkation for home, and cannot be taken to represent any special incidence of the disease on the station or the Command. The death-rates of European troops, native troops, and prisoners during the year were in the proportions of 5, 14, and 81 respectively.

Pneumonia and other Respiratory Diseases.—In 1902 the admission and death rates from pneumonia were much above the average, being 5·9 and ·97 per 1,000 respectively, but they fell in 1903 to 4·6 and ·57, the corresponding decennial means (1893-1902) being 4·2 and ·64 per 1,000. The more favourable results were almost entirely due to the diminution of the disease, and especially of the case mortality, in the Punjab Command, where, as a rule, the incidence is highest, and the Upper Sub-Himalaya group (VI) takes the first place this year as in the previous one. Attock Cantonment, where the range of temperature is very great and the winter temperature very low, furnishes rates this year of 35·7 and 8·93 per 1,000, which are unequalled in any other station. For the country as a whole the months of maximum prevalence were January and February, while fewest cases occurred in July, August and September. It may be noted, for comparison with the decennial means given above, that the corresponding rates for native troops were, admissions 14·7, and deaths 3·31 per 1,000, that is, three and a half and five times greater, respectively.

There was a slight decrease in the admission-rate from other respiratory diseases as compared with the previous year, viz., 20·5 against 22·5 per 1,000, the corresponding death-rates being ·21 and ·25 per 1,000, and here again it is the decrease in the Punjab Command which accounts for the difference. As regards the geographical groups, Burma Coast (I) and Bengal-Orissa (IV), where influenza was at its worst, yielded the largest number of cases in proportion to strength, and the stations to which this statement applies were Sitabaldi, Rangoon, Shwebo, Poonamallee and Kasauli, all with admission-rates above 50 per 1,000.

Dysentery and Diarrhœa.—There has recently been a steady diminution in the admission-rates on account of dysentery; the mean for the period 1896-1900 was 30·7 per 1,000, and this has fallen in the three succeeding years to 21·3, 20·4 and 16·9 respectively, the corresponding death-rates ranging from 1·10 for the quinquennium quoted to ·70 in the year under review. The Burma district in 1903 takes the highest place, which is usually occupied by the Bengal Command, while the Punjab has the lowest admission-rate, and Bombay the lowest death-rate. The table on page 40 will afford the best view of the contrasts in the incidence on the different geographical groups. As a rule, the disease is most prevalent during the height of the monsoon rains, but this year the maximum incidence tended towards the drier months, in Bengal, April, in Madras, May, June, and July, in Bombay, August and October, and in the Punjab, December. Barrackpore (151·1) and Poonamallee (120·6) had the largest number of cases in proportion to strength, and Rangoon and Naini Tal reported the highest death-rates, 9·6 and 7·04 per 1,000 respectively. At Barrackpore, which has a most unenviable reputation for the disease as well as for abscess of the liver, there has been a marked decrease during the past two years, but to judge from the special report of the Sanitary Officer (Major Aldridge, R.A.M.C.), much remains to be done on the lines laid down in previous paragraphs for the prevention of enteric fever, before hope of a permanent reduction can be entertained. At Rangoon the results were attributed chiefly to the youth and carelessness of the new arrivals, especially band boys, and to the impure food and milk indulged in.

The admissions on account of diarrhœa in 1903 yielded a rate per 1,000 of 13·5, as compared with 12·9 in the previous year, but no fatality was recorded. There is no great difference in the incidence of the disease on separate Commands, the Punjab taking the highest place, but as regards the geographical groups, Burma Coast (I) and the hill stations (XII *a*, XII *b*) have far higher rates than all the

rest. In the last named are included the stations with the highest ratios, viz., Ranikhet (71·3), Naini Tal (70·4) and Kasauli (64·8).

Hepatic abscess.—In 1902 the sickness and mortality from abscess of the liver were above the average as represented by the means for the quinquennium (1896-1900), viz., 2·3 and 1·36 per 1,000 respectively, but in 1903 there is a return in the right direction, rates of 2·4 and 1·29 being recorded. The Bengal Command, as usual, and its constituent geographical groups (IV and VIII) stand apart at the head of the list, and the stations most severely affected in proportion to strength were Barrackpore and Naini Tal, as was the case in the previous year. Allusion has been made to the excessive prevalence of dysentery in both these cantonments, and the connexion of the two diseases is notified in the majority of the cases of liver abscess reported this year, or, more exactly, in 71 per cent. of those occurring in the chief endemic centres. The type of dysentery prevailing at Barrackpore is said to be the "amœbic," and the medical officer reports that the "*Amœba dysenteriæ*" was found in the pus of all but one of his cases. Having regard to Schaudinn's work on the differentiation of the "*Entamœbæ*," one could have wished for a more definite and detailed description of the parasite recovered in these cases of both dysentery and abscess. Dinapore, Agra and Indore may also be mentioned as being affected in excess of the average, and it may be added that where fuller results of post-mortem examinations are reported, multiple abscesses were found in a majority of the fatal cases.

Alcoholism.—There were five deaths from alcoholism in 1903, against eleven deaths in each of the two previous years; the average number recorded annually during the decennium ending 1900 was seven, so that the figure for the year shows an improvement.

Venereal Diseases.—The admission-rate for all classes of venereal disease in India in 1903 was 247 per 1,000 of strength, against 281·4 in the previous year and 276 in 1901, and one must go back 24 years (to 1879) to find a lower rate than that of the year under review. The slight rise in the rate of 1902 was therefore only a temporary break in the phenomenal and consistent diminution which the records exhibit since 1895, when these diseases attained their maximum prevalence in the returns, viz., 522·3 per 1,000. The causes of this reduction of the rate by more than half its amount during the last eight years are various, and many of them are not obscure, if, however, it be impossible to appraise their relative values. Up to 1895, one effect of the short service enlistment was to introduce a large number of young men into Indian cantonments every year with all the consequences resulting from freedom from a sense of personal responsibility and ample opportunities for indulging their imperious impulses; then for about ten years before the date mentioned the lock-hospital system had been abolished, and in view of the state of medical opinion at the time, this doubtless resulted in a sense of helplessness on the part of the authorities, medical and other, in face of the situation thus created. There was perhaps some lack of adaptation of resources to meet it and possibly treatment of infected men, as of course of the women, was not adequately carried out, and thus it is not difficult to trace the results in the steady increase of the disease to the maximum during the decade in question. The slight decrease in 1896 is probably insignificant, but in 1897-98 three factors were in operation, one temporary, viz., the Tirah campaign, which withdrew large numbers of the men from cantonments; the others, which have existed ever since and have operated with ever increasing effect, were the new cantonment rules formulated as the result of the deliberations of Lord Onslow's Committee, and the system of treating many of the infected men as out-patients. Of the two last measures, the former aims at the expulsion of the diseased women from the neighbourhood of cantonments if they refuse treatment, and this has apparently met with varying and uncertain success; the latter has undoubtedly had two results at least; it keeps an uncertain number of cases out of the returns which formerly would have appeared therein, and it ensures better and more thorough treatment. It should, however, be noted that the cases so treated are largely convalescents previously reported, and also recurrent cases which under the old system would count as re-admissions, and so swell the returns beyond the actual number of fresh infections. So far, then, this new system has effected a decrease in the amount of disease reported, and beyond this, a real decrease by virtue of the better treatment it ensures which also reacts

by diminishing the number of sources of infection. In addition to these main factors there have been other influences at work, some fortuitous, and many of great value, and of more promise, as they are based on a truer recognition of the problem involved. The Boer war involved a great decrease in the annual drafts of young men for two years (1899-1901), and the prevalence of plague in native communities has caused many towns and villages to be put out of bounds for the troops. But there can be no question that the influences tending to the moral and physical amelioration of the soldier's lot have been greatly developed in the last few years by the combined efforts of the medical and military authorities. And this points the way to progress in the future; we must look to education of the men who suffer largely through ignorance and lack of self-control which are the results of the environment from which they are mostly drawn, and the lectures which are now a feature of many regimental institutes are a sign that this is becoming appreciated; to the provision of other healthy interests for the men's leisure, games, athletics, evening amusements and club comforts with, perhaps, encouragement of trade occupations or craftsmanship. And with all, the application of measures with sympathy to enlist the confidence and efforts of the men themselves, both in regard to prevention and treatment. This last will also apply to the women, for whose treatment ample provision should be made, for indications are not wanting that very much depends upon this and upon the methods adopted in working the rules applicable to them. Difficulties will not all disappear forthwith, but sympathy and other resources are not exhausted, and it is clear that a too arbitrary and indiscriminate exercise of authority leads to evasion of the code rules, to clandestine prostitution and to concealment and dissemination of the disease in other places, by both men and women. Lastly, it may be said that the measures for the prevention of the results of the importation of the disease from one station to another may be susceptible of improvement; and this by more complete notification between cantonment authorities, by greater care of, and influence exercised over, the men upon the march and those newly arriving. There must be co-ordination of resources, together with a definite policy adopted to the circumstances of each locality, and concentration of effort on the true lines of attack; for this, it is all-important to recognise the facts that certain of the men are specially liable to get into trouble, and that the danger is greatest at special times, in certain places and under special conditions, on all of which aspects the records throw light.

During 1903 there were 1,569·49 constantly sick on account of venereal disease, or about 140 more than in the previous year. The average period of detention in hospital for each case was 32·92 days, and the total loss of service involved amounts to 572,864 days, or 50,607 days in excess of the loss for 1902. The non-efficiency thus reckoned amounts to seven and a half times as much as that incurred on account of enteric fever.

There were 10 deaths (·14 per 1,000 of strength) directly due to venereal disease against 15 (or ·25 per 1,000) in 1902, and the number invalided for this cause was 213 (3·02 per 1,000) as compared with 310 (5·12 per 1,000). The results in invaliding this year, the lowest since 1889, have probably a direct connexion with the improved and more continuous treatment to which the men are now subjected.

Heat-stroke.—The death-rate from heat-stroke was approximately the same as in 1902, viz., ·77 against ·76; a considerable decrease in the Punjab and Madras Commands being balanced by a rise in that of Bombay. The stations chiefly affected were Nowgong, Nasirabad, Delhi, Fort Lahore and Lucknow.

Suicide.—The average annual number of suicides reported in the decade 1891-1900 was 19, and in 1903 there were 21, of which 12 were by gunshot, 4 by cut-throat, 2 each by drowning and hanging and one by oxalic acid poisoning; the means adopted maintain generally their relative positions in the list.

Invaliding.—From the whole European army in India, 2,063 men were invalided in 1903 (29·29 per 1,000 of strength, against 2,255 in the previous year (37·25 per 1,000). The millesimal rates ranged from 34·45 in the Madras Command to 25·39 in the Punjab, and there was a reduction in every case as compared with the previous year's results, which was most marked in the Burma district, and in the Punjab and Bombay Commands; the significance of these results has already been referred to. Fifty per cent. of the total number invalided were under 25 years of age, an age-period in which 51 per cent. of the total strength was included; 88 per cent.

of all the invalids were under 30 years of age, a category which comprised 86 per cent. of the total strength. Then as regards the effect of service in India, it is found that 30 per cent. of all invalids in 1903 had less than two years' service, a term which included 43 per cent. of the strength, and 64 per cent. of all invalids had been less than five years in the country, a condition that applied to 76 per cent. of the strength. As compared with the previous year there was a greater loss on this account among the younger men and among those of shorter service in India; it is true that in both respects there was a considerable increase in the proportions these classes bore to the total strength, but the proportions invalided were still higher. Sickness and mortality fall proportionally more heavily on the shorter service periods as compared with the lower age-periods, but the reverse is the case as regards invaliding.

Officers.—The average strength of commissioned officers with European troops in India in 1903 was 2,190, and among these there were 1,781 cases for treatment, 92 were invalided, and 29 died during the year. While the admission-rates from enteric fever, intermittent and remittent fevers, pneumonia, diarrhœa and hepatic affections generally showed a decrease, there was a rise in those from influenza, cholera, tubercle of the lungs, other respiratory diseases, dysentery and venereal affections. There were eight deaths from enteric fever, the chief cause of mortality, giving a rate per 1,000 of 3·65, which is lower than that for the troops (4·19), and a considerable decrease on that of 1902, viz., 6·21. Dysentery was, however, more fatal this year, five deaths having occurred in place of two in 1902. As compared with the incidence on the troops, the following diseases were more prevalent in proportion to strength, viz., influenza, small-pox, enteric and remittent fevers, dysentery, diarrhœa, and inflammation of the liver, while the officers suffered less from cholera, intermittent fever, tubercle of the lungs and all other respiratory diseases, hepatic abscess and venereal diseases, their comparative immunity from the last-named determining the difference in the respective combined admission-rates Heat-stroke, circulatory and "other respiratory" diseases, and dysentery and diarrhœa were the only chief causes of mortality which were more fatal to officers than to men. Two cases of plague occurred, but neither proved fatal.

Women.—There was a very slight improvement in the health of the women during 1903 as compared with the previous year, but still some falling-off from the results of 1901. The chief causes of admissions to hospital were, as usual, debility, ague, the diseases peculiar to women and bowel-complaints, which together accounted for 65·50 per cent. of all sickness. There were in all 41 deaths (14·18 per 1,000), of which enteric fever accounted for 7, intermittent fever for 4, cholera and pneumonia for 3 each, and dysentery for 2, yielding rates which are higher than those of the troops, for the second and third named causes only. The Burma district and Madras Command had the highest sick-rates, while in the former along with the Bengal Command the mortality was greatest.

Children.—The health of the children showed an improvement as compared with the previous year, but was somewhat less satisfactory than in 1901. The chief causes of sickness during the year under review were, as is usual, intermittent fever (20 per cent. of total), respiratory diseases (12 per cent.), diarrhœa (9 per cent.), and measles (6 per cent.); diarrhœa and enteric fever were more prevalent than in 1902, but the latter was only a little more than one-fourth as prevalent in proportion to strength, as it was among the troops. Out of a total of 173 deaths, diarrhœa was accountable for 31, anæmia, debility and immaturity at birth for 17, respiratory diseases for 17, dysentery for 13, and intermittent fever for 12, altogether for 52 per cent. of the total mortality; and intermittent fever, dysentery, tubercular diseases and cholera were all more fatal than in 1902. Among the exanthemata to which children are liable and which came under treatment during the year, were measles (145 cases), chicken-pox (94), rubella (8), scarlet-fever (5), small-pox (3); there were also 30 cases of mumps, 29 of whooping-cough and 11 each of diphtheria and dengue. Sickness and mortality were alike greatest in the Madras and Bombay Commands.

Native Troops.

Sickness and mortality in 1903.—The health of the native troops during 1903 must be regarded as exceptionally good, for the admission and constantly-sick-rates were the lowest on record, and the same may be said of the death-rate if the fatalities among men absent on furlough and sick-leave be disregarded. The average strength present in India was 124,660, and the following statement affords a comparison with the previous year and its antecedent quinquennium. This favourable result is to be ascribed to diminished prevalence of all the chief causes of sickness and mortality, although, as compared with 1902, there was some increase in the admission-rates for influenza, cholera, enteric fever and tubercle of the lungs, and in the death-rates from cholera and enteric fever.

Year.	Average strength.	Ratio per 1,000 of Strength.		
		Admissions into hospital.	Constantly sick.	Deaths.
1897–1901	126,127	794	31	11·92
1902...	124,231	718	27	11·16
1903...	124,660	662	25	10·04

The chief causes of sickness in 1903 were, as usual, intermittent fever, dysentery, venereal diseases, other respiratory diseases and pneumonia, in order of their relative prevalence, the first-named accounting for 37 per cent., and dysentery for nearly 6 per cent., of the total admissions to hospital. The chief causes of death were pneumonia, remittent fever and tubercle of the lungs, from which 30·5 per cent., 8·8 per cent., and 6·8 per cent., of the total mortality were recorded, respectively. The total number of men invalided for discharge during the year was 1,395, against 1,430 in 1902, the chief causes of this source of loss being, as usual, debility, intermittent fever, venereal disease, and rheumatism.

The native troops sufferent less than the European troops from small-pox, enteric fever, simple continued fever, diarrhœa, hepatic affections, and venereal disease, but, on the other hand, they were more liable to all the other chief causes of sickness, as also from scurvy, and this is in accordance with the usual experience. As regards sickness the great contrast lies in the relative incidence of venereal disease and enteric fever, and as regards mortality, while enteric fever and hepatic affections hold the first places among the European death-rates, pneumonia, remittent fever and dysentery are the diseases most fatal to their native comrades.

The strength of the China Garrison during the year was 1,745; the admissions to hospital, for which ague, influenza and venereal diseases were the chief causes, gave a ratio per 1,000 of only 298, as compared with 400 in 1902. The death-rate also fell from 13·83 to 12·03 per 1,000, and more than half of this was due to tubercle of the lungs. The Somaliland Field Force (strength 3,174) suffered chiefly from scurvy; ague, and pneumonia, the two former together accounting for 40 per cent. of all admissions, and the first and last combined for 37 per cent. of all mortality; altogether, the cases admitted for treatment amounted to 1,129 per 1,000 of strength, and the deaths to 25·83 per 1,000, but 17 men were killed in action, and if these be excluded, the death-rate falls to 20·4 per 1,000. The Aden Column Field Force (strength 983) had altogether 893 admissions to hospital or 908 per 1,000, ague and dysentery causing 60 per cent. of the whole, and there were 11 deaths, or 11·19 per 1,000, of which 6 were due to pneumonia. Sikkim-Tibet Mission Force which left India in March, and of which the average strength, calculated on an annual basis, was 929, had altogether 841 cases of sickness and 11 deaths up to the end of the year, and the ratios per 1,000 per annum were, therefore, 905·3 and 11·84, respectively; ague and dysentery were accountable for nearly half the former, and remittent fever for nearly half of the mortality. These details, summary as they necessarily are in the present state of the information available, serve at least to show the very various

conditions of climate to which the men are liable to be exposed, and the results must be considered eminently satisfactory, in view of the sensitiveness of the sepoy to any marked change from the conditions of his native habitat.

Commands.—In conformity with the results of the three previous years, the Bombay Command, in 1903, had the highest rates in regard to both sickness and

* Excluding troops in China and Somaliland, and including troops in Extra India not in the Indian Command, and also including Delhi Coronation Durbar Force, Sikkim-Thibet Mission, and Aden Column Field Force, which are not included in the commands.

mortality. There was less sickness in proportion to strength here on account of intermittent fever than in the Burma district and less from pneumonia than in the Punjab, the admission-rates from tubercle of the lungs and from simple continued and remittent fevers were also well below the average for the rest of India, but in most other respects there is an excess, and notably under venereal disease, diarrhœa and other respiratory diseases. Respiratory affections, bowel complaints and anæmia and debility are chiefly accountable for the higher mortality. The Punjab Command ranks next in order of unhealthiness, as was the case in the previous year, and this is due to the excessive sickness from remittent fever, tubercle of the lungs, pneumonia and dysentery, and to the higher mortality on account of the first three causes, and from cholera. The predominance of these affections is typical of the Punjab returns, as a rule, and explains the position of this Command at the head of the mortality list when a sufficiently long period, to obviate temporary fluctuations, is considered.

Geographical groups.—There were very great contrasts, as usual, in the incidence of sickness and mortality on the troops located in the different geographical groups. Taking the combined figures for the last quinquennium (1899-1903), the highest admission-rates were returned from Bengal-Orissa (IV), Burma Inland (II) and North-West Frontier and Indus Valley (VII), ranging from 1,035 to 881 per 1,000 of strength, the Gangetic Plain (V) and Upper Sub-Himalaya (VI) being at the other end of the scale with rates of 573 and 618 per 1,000, respectively, and this is notable inasmuch as the two latter areas constitute the natural habitat of the majority of the sepoys in the service. The contrast is chiefly due to variations in the incidence of intermittent fever. In regard to mortality, during the same period, the first place is taken by Western Coast (X) with 14·72 per 1,000, closely followed by the Hill Stations (XII) with 14·53, and then by the North-West Frontier (VII) with 13·82, while Assam (III) and Burma Inland (II) are at the other end of the scale, with rates of 7·47 and 7·45 per 1,000, respectively. Here the contrast is chiefly ascribable to the greater prevalence and fatality of pneumonia and other respiratory diseases and of remittent fever in the former areas, to which may be added an excessive mortality from bowel-complaints in group X. In this last the average strength is low,* but as regards the other two groups (XII and VII) climatic causes, and notably a high range of temperature with sudden falls and a very low thermometer at night for several months in the year, are sufficient to account for the results when the native disregard for ventilation is borne in view. It may be added that in 1903 there was no marked change in the order based on past experience. It is important to grasp the fact that the men serving in these two areas are for the most part strangers in a foreign land, the climatic and other conditions of which are very different from those of their homes. The Hill Stations (XII) are dotted along the fringe of the empire, at various but always considerable altitudes, from Burma at one end, through Assam and along the lower Himalayan range in the north, and thence along the North-West Frontier to Quetta in the west. The position of the other group (VII) is indicated in its name,—North-West Frontier, Indus Valley and North-West Rajputana, and nothing need be added to what has been said in regard to it. But it is advisable to distinguish as regards the Hill Stations (XII), between those on the northern frontier (Himalayan) and those on the north-western and western frontier from Chitral to Quetta, because the contrast with the natural climatic conditions of the plains of India proper is greater in the latter than in the former sub-group. Taking the mean results for the last triennium (1901-3), a period free from war operations, it will be found that while the combined admission-rate per 1,000 of strength (all causes) was 636, and the death-rate 8·8 in the first series of Hill stations, it was 988, and 17·4 per 1,000 respectively for the second series, *i.e.*, 50 per cent. more sickness and about 100 per cent. more mortality. Thus the North-West and Western Frontier and the Indus Valley stations stand out as the most unfavourable to the health of the native army, and the facts are of sufficient importance as to warrant a more detailed statement of the contrast.

---

* There are only three stations in Group X, viz., Bombay, Cannanore and Trevandrum; the average annual strength during the period in question was just over 2,000, of which two-thirds were located in Bombay, and the majority of the men here were recruited in the Dekhan, Rajputana, and the Punjab.

Sickness and mortality of the troops in the Hill stations (Group XII); contrast of Northern stations with North-Western and Western Frontier stations—mean ratios for 1901–3.

—		Intermittent Fever.	Remittent Fever.	Tubercle of Lungs.	Pneumonia.	Other Respiratory diseases.	Dysentery and Diarrhœa.	Scurvy.	Anæmia and Debility.	All Causes.
Northern stations	A.	178·5	16·1	18·7	11·9	17·9	32·8	1·0	12·2	636
Maymyo to Kalabagh	D.	·72	·97	2·70	1·25	·28	·16	—	·16	8·8
N.-W. and W. Frontier	A.	436·9	23·8	6·2	24·8	42·8	80·9	8·3	23·2	988
Gilgit to Chaman	D.	·80	2·02	1·60	7·16	·53	·75	·4	·4	17·4

It will be seen how much heavier the incidence is on the latter group in regard to all the causes tabulated, save only tubercle of the lungs, and this departure from the contrast is due to the special liability to this disease of the Gurkhas who are, for the most part, located in stations in the former group (see page 69). The contrast here demonstrated is enhanced when the "absent deaths" and invalidings are taken into account. In the former, northern series of stations, the "absent deaths" in 1903 amounted to 1·67 and the invalidings to 10·59 per 1,000 of strength, whereas in the latter, western frontier series, these ratios rise to 4·66 and 12·17 per 1,000, respectively.

Stations and regiments.—There were only two stations which had an average strength of over 1,000 men in 1903, and in both the sickness and mortality was exceptionally heavy. At Mian Mir the death-rate was 29·17 per 1,000, of which just over one-half was due to cholera, and another fourth to pneumonia; and at Ferozepur the death-rate was 22·97 per 1,000, of which one-third was due to pneumonia and one-fifth to remittent fever. As regards stations occupied by smaller numbers of troops, if a list be made of the fifteen having the highest death-rates during the last five years, it will be found that on the average, eight of the stations which are situated on the North-West or Western Frontier appear in the list every year, pneumonia and remittent fever being chiefly accountable for the excess mortality. Among the regiments with the most unhealthy record during the year, and to which reference will be made in the subsequent remarks, were the 104th Rifles at Fort Sandeman, who suffered chiefly from ague, pneumonia and scurvy; the 32nd Lancers at Loralai, from ague; the 4th Rajputs at Wana, ague and pneumonia; and the 11th Lancers at Mian Mir, from cholera and ague.

Influenza.—The admission-rate on account of influenza rose from 2·1 in 1902 to 3·6 in 1903, while, as will be seen, the sickness from respiratory diseases, excluding tubercle of the lungs, was less prevalent in the army as a whole. The month of maximum prevalence during the past three years has been February, or somewhat in advance of the local epidemics affecting the European troops. The largest numbers of admissions were recorded among the men at Lansdowne, Dharmsala, Aurangabad, Dehra Dun, Kirkee and Jhansi, the Bengal and Punjab Commands being chiefly affected.

Cholera.—There were 135 cases of cholera in 1903, with 80 deaths, the incidence of attacks on strength being the same as among the European troops and the prisoners. The figures are an increase on the 26 cases and 15 deaths of the previous year, but the rates are only a little more than half the decennial ratios (1891-1900). The most considerable outbreak occurred at Mian Mir, whence 34 cases with 29 deaths were returned from three regiments, the 11th Lancers having 22 and 17 of these, respectively. The disease broke out in June and lasted a little more than a month, but the great majority of fatalities occurred within one week of the outbreak, the type of attack being very severe. No remarks are offered by the medical officers concerned on the etiology of the epidemic, but from the sanitary report on the cantonment it would appear that infection was attributed to the use for drinking purposes of canal water

which is liable to pollution by native civilians, no protected pipe supply being yet available as in the case of the European garrison. Twenty-one cases with 8 fatalities occurred among the 77th Moplah Rifles at Salem in January, the outbreak commencing while the regiment was on the march, and it was attributed to the consumption of infected water or food in the native bazaar. In a detachment of the 128th Pioneers which was posted as a cordon round a cholera-infected village, there were 18 cases with 7 deaths in June, and in the same month also and in the same area (Baluchistan frontier) the 113th Infantry had 12 cases and 7 deaths for which details are lacking; the disease was, however, epidemic in the villages in the neighbourhood.

Small-pox.—There were 78 admissions and 2 deaths from small-pox during the year, the rates per 1,000 of strength being precisely the same as for 1902; while the rate of attack is slightly above that for the decennium (1891-1900), the mortality rate is decidedly less. The disease was less prevalent than among the European troops, which is contrary to previous experience, and it was far less fatal, which is according to the general rule. The largest number of admissions, 8, was reported from Cannanore, all among the 87th Punjabis; there were 7 at Lucknow and 6 at Umballa. The records are incomplete as regards the discussion of the sources of infection and the previous vaccination of the men attacked, but so far as information is available, these all bore satisfactory marks of the prophylactic or, rarely, of a previous attack of the disease.

Ague, remittent fever, simple continued fever.—Intermittent fever accounted for over 37 per cent. of the total number of admissions for all causes in 1903, but the admission-rate which was 358 per 1,000 in 1901, and 274 in 1902, fell still farther to 242, which is just over 100 per 1,000 less than the mean for the decade, 1891-1900. From all but two of the twelve geographical groups the admission-rates were lower than in 1902, the two exceptions being Burma Coast (I) and Assam (III), Burma Inland (II) and Central India (VIII) being at the head of the list as was the case in the previous year; and the last remark applies to the Bombay and Punjab Commands and the Burma district. October was, as usual, the month of greatest prevalence of the disease when the records from the army as a whole are combined, and fewest cases occurred in March. Of the stations at which the average strength was over 100, those where the admission-rates were highest (exceeding 1,000 per 1,000) were Keng Tung (Burma), Deesa, Ahmedabad, Chakdara and Wana, the three first appearing in the same list in 1902. The plain of Keng Tung, 90 square miles in extent, with the highlands surrounding it on all sides, forms a huge natural basin of impermeable clay soil which is covered throughout its vast extent by rice swamps. The cantonment stands on the spurs of the low hills jutting into this plain, and its boundary includes the junction of hill and plain where many depressions and natural, but irregular, drainage channels abound. The annual rainfall is 75 inches, the ground water level is high and the whole plain is intersected by numerous water-courses. The barracks are of the bamboo hut type, and not much more than 500 yards from a "not over-clean" Shan village, while an Indian bazaar connects the two communities; the habits of the Gurkha sepoy are extremely sociable. Under these circumstances it is scarcely surprising that, in spite of the use of mosquito nets, 90 per cent. of the men have been under treatment for malarial fever, at one time or another. The physical difficulties prevailing at Deesa—the proximity of the Banas River, a small stream often reduced to stagnant pools in a wide sandy bed in which cultivation is carried on—were alluded to in last year's report. The accounts given of other notoriously malarious cantonments vary in detail; for example, at Dera Ismail Khan it is said that after heavy rain the city is flooded and the cantonment and its vicinity is under water; the drains that intersect the lines are mere earthen channels, with no proper and adequate fall, the difficulties being enhanced by the low-lying site. The situation at Delhi is very similar to that just described at Deesa. All this goes to show the physical difficulties that present themselves to any attempt to deal radically with the problem of the prevention of the breeding of mosquitoes in many of the stations, to which end efforts have been directed generally with more or less energy on the approved lines. The proximity of native civil communities and the intercourse of the sepoys therewith, must also be a frequent and an insuperable difficulty. And thus, along with the general sanitary measures that often fail to influence the prevalence of the *anopheles*, resort to the administration of quinine as a

prophylactic is generally practised though, in this matter, as in the case of the European troops, the methods and the system vary and the results, consequently, are, so far, too often inappreciable. Where nothing can be done to ameliorate the physical conditions, short of removing cantonments from their present sites, or of abolishing irrigation on which the food supply of the people depends, or of deflecting the courses of rivers, or of altering the whole configuration of the country, the efforts towards personal prophylaxis in cantonments and in hospitals must be systematized and carried out with energy and completeness, till the measures become ordered habits of the men's lives.

Remittent fever, to which more sickness and mortality is attributed among the native troops than among their European comrades or the prisoners was much less prevalent during the year; the mean admission-rate for the decade (1891-1900) was 15·2 per 1,000, and the death-rate 1·25, whereas the rates fell in 1903 to 8·6 and ·88 per 1,000, respectively; nevertheless, nearly 9 per cent. of the total mortality was attributed to this cause. Cases are generally most numerous in the dry hot spring and winter, and in 1903 the maximum prevalence was in January, though cases were admitted throughout the year. The remarks of medical officers on the subject of the etiology of this form of fever are not very illuminating, and where the microscope is not systematically employed little could be expected. It would appear that change to a more rigorous climate and to unaccustomed surroundings are important factors in inducing attacks, and the regiments that suffered most were, in many instances, exposed to these conditions, *e.g.*, on the North-West Frontier, in the Indus Valley and on the Sikkim-Tibet expedition. The incidence was by far the heaviest on the Punjab Command, and on groups III, VI, VII, and XII, and this is in accordance with previous experience. It may be added, in connexion with the marked progressive decline in the admission-rates alluded to above, that where these have been consistently lowest, as in the Madras Command, the decrease is inappreciable during the past ten years, and it may be that more exact diagnosis, or that a question of nomenclature has had some influence on the returns from elsewhere. For it is remarkable that with this low remittent fever rate, the Madras Command has always returned the highest number of cases of simple continued fever in proportion to strength, just as the Punjab with the highest rate from remittent has always been at the bottom of the list for the simple continued variety.

As regards this simple continued fever the decline in the reported incidence has everywhere been still more marked than in the case of remittent, the mean admission-rate for the whole army having been 9·1 per 1,000 during 1891-1900, while in 1902 it was 5·1, and in 1903 it fell to 3·5. Against the last figure may be set the rate for the Madras Command, 12·6, and that of groups XI (Southern India), 30·5, to show how large a proportion of the disease is accounted for in a comparatively small area. Indeed, out of a total number of 441 admissions throughout India during the year, no less than 153 were recorded in one regiment, at Bellary, the 74th Punjabis, consisting of men who were recruited in Northern India at the end of 1902. Here we may, perhaps, see the effects of a complete change of climate inducing ephemeral fever, during the period of physiological adjustment, or possibly malarial relapses.

Enteric fever.—The admission-rate on account of enteric fever has shown a tendency to a small but regular and definite increase during the last few years. During the first three lustra with which the records deal, *i.e.*, up to 1891, the rate

Enteric Fever—Native Troops.	Ratios per 1000.	
	A.	D.
1877–1891	·21	·09
1892–1896	·25	·06
1897–1901	·3	·11
1902	·4	·10
1903	·6	·22

per 1,000 did not vary materially from ·21, and the death-rate was approximately ·1, a case mortality of nearly 50 per cent. The subsequent course of the incidence of the disease is shown in the above summary; it will be seen that the rates have exactly doubled within the last six years. It is difficult to decide how much of this reported increase connotes a real extension of prevalence, and how much is due to altered diagnosis, and it is not impossible that a certain amount of what was formerly returned as remittent fever has found a place under this head; for with the diminution of remittent fever, already noticed, there has also been a reduction of the case mortality from both diseases, which might be accounted for on the suggestion hazarded. An important point which the returns bring out clearly is the much greater incidence of enteric fever on the Gurkha sepoys,* and, further, its comparative localization in the cantonments occupied by them. For instance, during the last four years, 107 cases have been recorded among the Gurkhas, with an average annual strength of 11,458, yielding a mean rate per 1,000 of 2·3, whereas from the rest of the native army, annual average strength 112,332, only 103 admissions were reported, or ·22 per 1,000, which is just under one-tenth of the Gurkha rate. Again, to turn to the year under review, of the total of 80 cases reported, 37 were distributed among the Hindustanis (·32 per 1,000) while 43 remain for the Gurkhas (3·4 per 1,000) and these 43 were reported from 7 stations, whereas the other 37 were the contributions of 24 stations, of which 21 recorded only one case each. These facts explain the relatively heavy incidence of the disease on geographical groups III and XII (Assam and the Hill stations), and beyond this, it may be said that in the greater part of the native army (Hindustanis), the disease, if present, is not recognised, or, at most, in negligible quantity. The possibility that the disease is truly more prevalent but is concealed in the returns under one or other of the common fevers is, as was shown in this report for last year, rendered less plausible from the fact that the combined death-rate from these fevers, including enteric, is very much lower among the natives than it is among the European troops; and this could only be the case on one of two

——	European troops. Deaths per 1,000, 1903.	Native troops. Deaths per 1,000, 1903.	Prisoners. Deaths per 1,000, 1903.
Enteric fever	4·19	·22	·25
Intermittent fever	·34	·66	·94
Remittent fever	·4	·88	·36
Simple continued fever	·01	·01	·01
Total fever mortality	4·68	1·77	1·56

hypotheses. Either enteric fever is not overlooked to any material extent, or the disease runs a much milder, a very anomalous, and less fatal course among the natives. It is quite true that so-called remittent fever is much more fatal to native troops and prisoners than to Europeans; it is true, further, that the remittent fever rates have recently fallen coincidently with a rise in the enteric rates among the two former classes. But if the whole of the mortality from remittent were transferred to the account of enteric, it would still leave a great balance of comparative immunity from the latter disease, in favour of the native adult. It is to be noted that the remittent fever rates are consistently lower among the prisoners than among the native troops, but there is no corresponding excess in the enteric rates among the former. Methods of diagnosis may undoubtedly affect the contrast in the remittent rates in the different classes; there are fewer cases in proportion to strength diagnosed as remittent fever among the prisoners, but there is a higher case mortality of those so diagnosed than among the native troops, but the enteric rates are practically identical in the two classes; and as regards fatal cases of both diseases among the prisoners, the great

* The increase in the rate already noticed is common to both Hindustanis and Gurkhas, but is much more marked among the latter.

majority are submitted to an autopsy, which should preclude any large source of error. Lastly, the age factor can scarcely be invoked to explain the whole difference in this respect between the native and European troops; the age constitution of the former is, unfortunately, not available, but it would doubtless be found that there is a smaller proportion of the strength at the most susceptible ages among them and by so much the incidence would be reduced, if we may presume that the ages of susceptibility are the same in both.

It must be admitted that the evidence which is relied on in the diagnosis of enteric fever among natives is, for the most part, clinical, in which a process of exclusion of other causes plays a large part, and, in the case of prisoners, this is supplemented by the signs of gross pathological changes found post-mortem. Beyond this, there is the accumulating evidence based on the results of the Widal reaction, which was fully summarised in this report for 1901. It is obvious that a diagnosis which in the present stage of the question, is made on clinical grounds or from the gross pathological signs is frequently open to grave doubt, if only from the risk of overlooking cases that present no typical intestinal lesions. It is, therefore, eminently desirable, nay necessary, that medical officers should avail themselves in all cases of doubt of the facilities now at their disposal for the application of the more exact and reliable tests of the blood and excreta during life and of the organs after death. It is only by the employment of these methods that an escape will be found from the cloud of conjecture in regard to enteric fever itself, and that we may hope to elucidate the causes of other anomalous fevers.

As to the causes of the special liability of the Gurkha sepoy to the disease, nothing can be added to the discussion of the subject in previous issues of this report. In regard to etiology, the medical officer of the 2nd battalion, 3rd Gurkha Rifles, among whom 13 cases occurred, attributes the infection to polluted spring water in which the *bacillus coli* and the *bacillus enteritidis sporogenes* were demonstrated. At Manipur, polluted river water was suspected, the separate supply for drinking being accounted beyond suspicion as it was boiled before issue. In other cases bazaar milk and fæcally contaminated dust were suspected, and it is noted that the sepoy is addicted to the dangerous practice of cleaning his eating and cooking vessels with surface soil from the handiest spot.

Malta fever.—Eight cases of Malta fever were recorded during the year, against four in 1902, but of only three are details given as to the symptoms and the grounds on which the diagnosis was based. The two cases among the 15th Sikhs at Fort Lockhart were originally admitted for intermittent and remittent fever, but on subjecting the blood to the sedimentation test complete reactions were obtained with dilutions of 1 to 50 and 1 to 200, respectively; the source of the micrococcus used is not stated.

Plague.—The incidence of plague on the native troops cantoned throughout India has been as follows: in 1898, 94 cases with 54 deaths; 1899, 76 and 45; 1900, 56 and 29; 1901, 70 and 41; 1902, 192 and 95; 1903, 184 and 115. The great extension of the disease among the civil population, during the year under review, has therefore not been accompanied by a corresponding increase among the native troops. Out of the total of 184 stations occupied, 57 were situated in or near towns or in districts in which plague occurred among the general population, but of this 57 only 24 had cases among the sepoys. The largest number of attacks reported from one station was 26 at Bangalore, and these were distributed among four different corps. Very few details are given of this outbreak by the medical officers concerned, but the disease prevailed in epidemic form in the civil and military lines and there was doubtless constant communication with the infected area either direct or indirect by means of followers, tradesmen, &c. Mention is made of the prophylactic inoculation of 681 volunteers in the 28th Light Cavalry in which one case only occurred, and of two cases of plague in the Moplah Rifles, one who had been inoculated, recovered. The only other considerable outbreaks occurred in two regiments at Aurangabad (21 cases, 7 deaths); at Poona (18 and 10); Mhow (16 and 14); Sehore (14 and 9); and Neemuch (10 and 3); on the other hand, in 5 stations there was only a single case in each, and in 4 others, 2 cases in each. The reports call for no comment; sources of infection were, in all cases, abundant in and around cantonments; the measures adopted consisted, generally, in putting infected places out of bounds for the troops, the segregation and observation of men arriving, or returning,

from infected places; and on the outbreak of the disease, prophylactic inoculation for all willing to accept it, including followers and families, segregation of the sick, evacuation of the lines by the healthy and temporary sojourn under canvas, and all measures of disinfection of infected quarters and of the lines and barracks. It may be said that the consensus is decidedly in favour of the beneficial effects of inoculation in reducing the liability to attack and also the case mortality, but the details given in each case are rarely complete and scarcely permit of a summary which would have scientific value.

Cerebro-spinal fever.—As in the case of the prisoners, cerebro-spinal fever has notably decreased during the last year, there having been only 6 cases with 4 fatalities recorded from the whole native army, against 18 and 17, in 1902, and 28 and 21, respectively, in 1901. The disease has been most prevalent in the Punjab Command and on the frontier, but not confined thereto, and this year the six cases were reported, one each, from Kohat, Edwardesabad, Delhi, Jhelum, Roorkee and Mhow. No reference is made to the etiology or diagnosis of these cases in any of the returns.

Tubercle of the lungs.—It is interesting to compare the incidence of tubercle of the lungs on the European troops, the native troops and prisoners, respectively, during the last year and the previous quinquennium. While on the mean for the longer period the rates for the native troops, and especially the death-rate, are higher than those of the Europeans, they compare very favourably with those of the prisoners. But there has been a very notable rise in the amount of the disease reported among the native troops, though the mortality remains fairly stationary; for instance, the mean admission-ratio for the decade ending 1900 was only 2·8, and the death-rate ·69, and the former has since then gradually risen to just over twice

Tubercle of Lungs—India.	Ratios per 1,000 of Strength.			
	1898–1902.		1903.	
	A.	D.	A.	D.
European army	3·2	·55	3·4	·24
Native army	3·8	·76	5·9	·68
Prisoners	8·7	3·78	9·3	3·85

the amount. It is probable also that many deaths occurred among men who were absent from their regiments, and these cases are not accounted for in the death-rate. Turning next to the distribution of the disease in place and on personnel and taking the returns for 1903, it will be seen first, that the case-rate in the Punjab Command is just twice as high as that for India as a whole (11·7 against 5·9 per 1,000), the quinquennial rates, however, give the Bengal Command an incidence equal to that of the Punjab; next, as regards the geographical groups in the year under review, the Hill stations (XII) stand out with a rate of 16·1 per 1,000, followed by Upper Sub-Himalaya (VI) with 7·9, all the rest being below the average. This unfortunate pre-eminence of group XII is chiefly due to the excessive incidence on the Gurkha sepoys, which is clearly shown by the following facts. There were altogether 730 cases with 85 deaths (excluding "absent" deaths) recorded in the whole native army in India during the year; but no less than 362 and 36, respectively, were reported from the Gurkha regiments, or about one-half of the total on little more than one-tenth of the aggregate strength. Putting this in terms of ratios per 1,000 of strength, it will be found that while for the native army as a whole, excluding the Gurkhas, the pulmonary tubercle rates were 3·2 and ·43, they were actually 28·9 and 2·8 per 1,000, respectively, for the latter class alone, the case incidence being 9 times and the mortality nearly 7 times greater.

There were only six cases returned as non-tubercular phthisis during the year, as compared with 23, with one death in 1902.

Pneumonia and other respiratory diseases.—Pneumonia is invariably the chief cause of death among the native troops, and in 1903 it accounted for over 30 per

cent. of the total mortality; a comparison with the incidence on the European troops and prisoners is given in the statement below, which extends back to 1891, and it shows what an important part the disease plays in the vital statistics of the two native classes. As regards the native army there has been little variation in the rates during the last 13 years, but the slight diminution reported in 1903, as compared with the previous year, is so far satisfactory in view of the increased prevalence of influenza already noted. A glance at the Table on page 63 will show how disproportionately heavy the incidence of pneumonia is on groups VII (North-West Frontier and Indus Valley) and XII (Hill stations), and these are followed at no great distance by VIII and VI, while Burma (I) stands at the other end of the scale, and this is according to the usual experience. This distribution will also explain the prominent position taken by the Punjab and Bombay Commands in the returns, and when it is added that the months of greatest prevalence were December, January and February, the effect of the low temperatures in the continental and more elevated areas will be evident. Natives of India, who are so universally subject to malarial infection, when aggregated in an unaccustomed climate are peculiarly liable to affections of the lungs, to which also their domestic habits greatly contribute; for their first impulse is to exclude the cold air by preventing ventilation and by covering their heads at night with blankets and quilts which are generally polluted with pulmonary excretion. The highest admission-rates are almost invariably returned from the hill stations on the North-West and West Frontier, and during the past year rates of over 50 per 1,000 of strength were recorded in Wana, Mirali-Khel and Fort Sandeman, and if the statistics for the triennium (1901-02) be analysed, it will be found that in the line of Stations from Gilgit to Chaman the troops had mean admission and death-rates of 24·8 and 7·15 per 1,000, respectively. Only little less susceptible are the men stationed just within the line of frontier outposts, and then the more or less aboriginal tribesmen who serve in the hilly tracts of Rajputana.

Pneumonia.	Ratios per 1,000 of Strength.					
	1891–1900.		1902.		1903.	
	A.	D.	A.	D.	A.	D.
European troops	3·8	·60	5·9	·97	4·6	·57
Native troops	14·4	3·24	15·3	3·7	14·4	3·06
Prisoners	16·2	4·27	13·2	3·38	13·6	3·62

The foregoing considerations apply very generally to the incidence and distribution of other respiratory diseases among the native troops, having regard to the fact that the list includes several different pathological conditions with no etiological identity. A retrospect shows that there has been a very considerable diminution in the sick and mortality rates under this heading since 1895, a feature which the statistics of the prisoners also exhibit. The state of the case as regards the native army may be appreciated when it is stated that the millesimal admission and death-rates for the decade (1891-1900) were 33·2 and ·61, whereas in 1903 they had fallen to 22·2 and ·21, respectively, which, indeed, are the lowest on record. The records invite no comment beyond the statement that the incidence in proportion to strength was greatest on the small Western Coast group (X), on the North-West Frontier and Indus Valley (VII) and the Hill stations (XII), while, in regard to individual stations, some of those on the North-West and Western Frontier stood at the head of the list in the past year.

Dysentery (I.) and Diarrhœa.—There has been a notable decrease in the sickness and mortality from dysentery during the last five years, a feature of the returns which has already been noticed as regards the European troops, and which those of the prisoners also exhibit in less degree. It will be seen that, in the case of the native troops, the admission-rate for the year has fallen by 25 per cent., and the death-rate by about 50 per cent., from the respective decennial means, and, indeed,

these are the lowest figures on record. As a general rule the highest admission-rates are reported from the Assam and Bengal-Orissa groups (III and IV) followed by the Burma groups, the North-West Frontier and Hill stations being also above the mean for India, and with slight modifications this order holds good for the year under review; this may furnish another instance of the fact that sickness is least prevalent where the sepoy is most "at home." Of the ten stations with a strength of over 100 men, where the admission-rates exceeded 100 per 1,000, four are situated in the hills and three in the Indus Valley, and the combined mean rate for the line of Frontier posts along the North-West and Western Frontier amounted to 65 per 1,000 during the last triennium.

Dysentery.	Ratios per 1,000 of Strength.					
	1891–1900.		1902.		1903.	
	A.	D.	A.	D.	A.	D.
European troops	29·6	·87	20·4	·69	16·9	·70
Native troops	48·8	·59	46 0	·39	36·6	·30
Prisoners	99·6	6·81	96·4	5·13	88·8	3·73

A very marked decline in the morbidity and mortality from diarrhœa has been a feature of the returns during the last six years, both as regards the native troops and the prisoners. For the former, the mean admission and death-rates for the decade (1891-1900) were 13·6 and ·26 per 1,000, but in 1903 the figures were 7·2 and ·10 per 1,000, respectively, the sick rate being the lowest on record. The relative distribution of the disease, under this name, which merely refers to a symptom, is very similar to that of dysentery, and it is in accordance with common experience that in 1903 the returns were highest from the Bengal-Orissa (IV) and the Hill stations (XII) groups. Medical officers of the cantonments where the disorder was most prevalent ascribe the attacks chiefly to chills and to indiscretions in diet.

Venereal diseases.—Venereal diseases were ten times more prevalent among the European troops during 1903 than among their comrades of the native army, there being only 24·5 admissions for this cause for every 1,000 men among the latter against 247 per 1,000 in the case of the former; the decennial mean rates (1891-1900) were 37 and 431 per 1,000 for the two armies, respectively. The "civil condition" of the two classes and the other conditions under which they serve are very different, and in the case of the natives we have no parallel to the extraordinary fluctuations in the rates which characterize the European returns. During the last quarter of a century the sick-rate from this cause for the native army has never risen above 42 per 1,000, and it has never fallen so low as that of the year under review, 24·5.

A few words may be devoted to the distribution of venereal disease in the native army; and first, it may be said that the Gurkhas invariably suffer in a much higher degree than the rest of the troops, while the sepoys in the Punjab Command show to great advantage in this respect, those in Bengal coming next, but at a very considerable interval. This comparative immunity is doubtless due to the fact that the men are serving close to their homes in these Commands. While the admission-rate for Gurkhas in 1903 was 38·7 per 1,000, it was only 13·6 for the troops (excluding Gurkhas) in the Punjab Command, and for the whole of the rest of the native army it was 27·1; so that, if the Gurkhas be excluded, the amount of sickness in proportion to strength is only half as great in the Punjab Command as in the rest of India, and statistics for a longer period confirm these relative positions in all essential respects.

Beri-beri.—There were 122 cases of beri-beri admitted during 1903, of which 8 were fatal, against 84 and 10, respectively, in the previous year; the disease was, as usual, practically confined to the regiments serving in the Madras Command. On the whole, there has been comparatively little variation in the incidence of the

disease reported,* either in amount or distribution for many years past, the average annual number of cases since 1894 being 120, and those occurring outside Madras or Burma being rare exceptions. This year no less than 113 cases out of the total of 122 were reported from three regiments, viz., the 63rd Palamcottah Light Infantry, which was stationed at Singapore and Vizianagram, 50 cases; the 73rd Carnatic Infantry, at Singapore, 47 cases; and the 81st Pioneers, at Secunderabad, 16 cases. The medical officer of the first-named corps leaves it to be inferred that the disease was acquired at Vizianagram, which has a bad record in this respect; as regards the second regiment, it is said that as the disease is endemic in the Malay Peninsula, the sources of infection were abundant at Singapore, but in neither case is any fresh light thrown upon the etiology of the sickness. The same remark applies to the outbreak at Secunderabad, though it is said that the majority of those attacked were recruits of under one year's service, and a similar liability of young men on first arrival has been frequently remarked in previous years' reports. At Secunderabad it is also noted that the quarters occupied by the men affected were evacuated, thoroughly disinfected and kept vacant, while special attention was paid to the diet; the rice supplied was found to be good and wholesome.

Jails of India.

Sickness and mortality in 1903.—The vital statistics of the jail population in 1903 present some striking features which, inasmuch as they are the culmination of a record of consistent progress, merit a more general discussion than is usually devoted to them in the text of this section.

The climatic conditions of the year were generally normal and favourable, save in respect of some defect and irregularity of the monsoon rains in June and July, their excess in August and September, and their late continuance in October. The harvests were, on the whole, abundant, and food prices steady and slightly lower than in 1902, but the health of the free population was less satisfactory, due chiefly to increased prevalence of plague and malarial fevers, the death-rates being everywhere higher than those of the previous year save in Bengal, and they were above the quinquennial standard everywhere save in Burma. The general prosperity, which is so directly dependant on the food-supply, was marked by a very notable diminution in the jail population, the aggregate strength, which had averaged 118,485 during the previous eight years, falling to 105,729, the lowest figure since 1890. The release of convicts on New Year's Day, in commemoration of the Coronation of the King-Emperor, certainly contributed to this result, but the chief factor was the large decrease in the number admitted into jail during the year, a decrease which amounted to about 30,000 on the total for 1902. Some acquaintance with the nature of the jail population is important for an appreciation of the vital statistics.

Special influences affecting the jail population.—In the first place, the connection of poverty with crime is specially obvious in this country. A marked feature of the past decade has been an extraordinary increase in the jail population altogether out of proportion to that of the people at large, and this is chiefly due to the conditions of famine and scarcity to which they have been subject; at the same time, the accommodation in the jails is limited. Any considerable strain on the food resources is marked by an increase of crime and sickness, the available accommodation of many of the jails is taxed, the prisoners are admitted in poor physical condition, and frequently suffering from disease. On the other hand, with a return of prosperity, fewer are admitted, these are in better health, and find the conditions of jail life, as regards aggregation, very much more favourable, inasmuch as the great bulk of the sickness and mortality is due to communicable (infectious) diseases.

Again, it is frequently said that the great majority of our prisoners is drawn from the agricultural classes, but these are, of course, in overwhelming

---

* The case mortality has, however, varied from 6 to 19 per cent.

overwhelming preponderance in the free population. A study of statement II.,* giving the previous occupation of convicts, does not permit any definite conclusions to be drawn upon this question, but in 1903 only 54 per cent. of the total admitted are reported to have been "engaged in agriculture, &c.," and it would appear that an excessive proportion of criminals is drawn from the towns, where the physical standard is at its lowest and where the lower classes have suffered specially from the general rise in prices. The fact that only 13 per cent. of those admitted are "habituals" must also be considered in the light of the numerical inferiority of the urban population. Lastly, we have to deal with a flowing and fluctuating population; the total number of convicts admitted and discharged during the year amounted to nearly three times the average strength, and the number of prisoners under trial who passed through the lock-ups was equal to 25 times the average strength,—facts of cardinal importance in view of the character of the diseases and their constant introduction from without. Comparisons of the death-rates in the jails with those of the free population are subject to fallacy owing to the defective registration of mortality among the latter, and in any case, they would require correction for age and class (or economic position), but a falling rate in the jails which is synchronous with a rising rate among the people at large is obviously to the credit of the former. And this is precisely the position disclosed, equally with regard to the past quarter of a century and to the year under review, when the statistics are viewed as a whole.

The record since 1881.—The last four quinquennial periods of the century just closed yielded the following death-rates per 1,000 for all classes of prisoners combined, viz., 35·96, 33·95, 30·63, and 29·97, the last being the period of famine and scarcity and of the prevalence of plague (1896-1900). Moreover, the average population, which was only just over 90,000 in the first lustrum, rose to 114,000 in the last, an increase of over 26 per cent. The death-rates for the last three years (1901-1903) were 26·87, 24·85 and 21·38, respectively, the whole series thus showing a steady and consistent decrease of mortality, representing a very large annual saving of life. The causes of sickness have remained unaltered in character and have diminished only slightly in amount, while the condition of prisoners on admission has been less favourable and the sources of infection from without more numerous.

It has been calculated that the mortality of males of the free population in India as a whole, under ordinary conditions, is at the rate of 25·8 per 1,000 of the number at the age-period 15 to 64 years, which may be held to cover the ages of the prisoners. At present the returns do not afford data for an exact comparison of the age-constitutions of the jail and free populations, but these could easily be obtained by a census of the ages of prisoners to be taken, say, on two days in the year, and it would be advisable to institute such a census.

The fact that the death-rate among prisoners, who are drawn chiefly from the lowest and least resistant classes, has fallen so notably below the standard for the free population at the same ages, will justify this review of the present position and a more detailed analysis of the figures that may provide a clue to past and future progress.

Convicts, long and short term; comparative statement.—As regards convicts, and excluding the Andamans Settlement, for which data are not available, a comparison of the results for 1903 with those of the average of the first lustrum in the period reviewed (1881-85) shows, that while the combined death-rate in all jails has fallen from 36·9 to 19·7, or 46 per cent., the share of the district jails in this result has been 34 per cent., while that of the central jails has been 58 per cent. With this is connected the fact that the reduction of mortality has been greater among convicts who had passed over six months in jail, viz., 51 per cent., than among those who had been detained for only six months or under, viz., 41 per cent. The death-rate of short-term prisoners is consistently highest throughout, due chiefly to their condition on admission, and to the arrangements in district jails, with a flow of population equal to four times the average strength, involving reintroduction of sickness. If we distinguish among the longer-term prisoners those detained for periods between six months and three years, and those detained over three years, it is found that the death-rate of the former, from being higher in the first period,

* Provincial Reports.

has gradually fallen to the level of that of the latter (longest terms), till 1903 the figures were 17·8 and 18·2 per 1,000, respectively, which become 16·04 and 16·8, respectively, in central jails taken alone. The average strength yielding these satisfactory results amounted to 50,000, or 60 per cent. of the total population, excluding the Andamans, and it is obvious that under present conditions, there is no great scope for future improvement in the life prospects of these prisoners.

Prisoners under trial.—As regards prisoners under trial, it is to be noted that the average detention in the lock-ups is only about 14 days, and there would appear to be some disinclination on their part to report sickness, for the hospital admission rates are consistently very much lower than those of convicts in all but two provinces (Burma and United Provinces). But not more than half their number are convicted, and the non-criminals probably represent a better physical type than that of the convicts. Among all, the stimulus of the hope of speedy release probably operates against complaints of sickness in the early stages, and this may be one cause of the higher morbidity and mortality which fall upon those who are convicted, and during their first six months' sojourn in jail. This would indicate the necessity of careful enquiry into, and early treatment of, all cases of sickness in the *hawalats*.

The death-rates of the prisoners under trial for the three quinquennial periods ending 1900 were 29·65, 28·93 and 31·26, the first two comparing favourably with the convict rates, the last representing the effects of famine and epidemic disease (1896-1900). The short period of detention implies less liability to fatal results from the more chronic forms of disease, and on the other hand, it may be less complete control of these prisoners on the part of the medical officers. The death-rates for the past three years (1901-1903) are very satisfactory, viz., 21·47, 20·11 and 17·9, respectively, the last figure, as in the case of the convicts being the lowest on record.

Turning next to the chief causes of sickness and mortality among the convicts, and comparing the results for 1903 with those of the first period under review, the returns yield the following analysis:—

Convicts.—Sickness and Mortality—Comparative Statement.

Convicts in India.	Admission and Death rates per 1,000.			
	1903.		1881–1885.	
	A.	D.	A.	D.
1. Malarial fevers	381·3	1·28	450·2	2·61
2. Tubercle of lungs	10·5	4·17	5·7	2·36
3. Anæmia and debility	9·7	0·31	28·1	2·26
4. Pneumonia	14·0	3·70	52·1*	5·83*
5. Other respiratory diseases	39·3	0·82		
6. Dysentery and diarrhœa	141·6	5·02	182·7	12·92
Total (*a*)	596·4	15·30	718·8	25·99
Total all causes (*b*)	911·7	21·75	1,099·5	35·96
Per cent. of (*a*) to (*b*) ...	65·4	70·3	65·3	72·2

* All respiratory diseases, including pneumonia.

This shows that at present, as formerly, 65 per cent. of all sickness and 70 per cent. of all mortality is ascribable to the causes specified above. And further, the reduction in the mortality from these specified diseases, from other causes and from all causes, has been approximately the same, viz., 41 per cent. While the general character of the sickness remains unaltered and its amount in the aggregate has been very slightly diminished, the case mortality has been very considerably reduced.

It is important to note that the diseases specified belong to the class of specific communicable infections, and that this list does not, by any means, exhaust the number of these to which prisoners are liable.

If, now, the evidence adduced be borne in mind, notably the special liability to sickness and mortality of short-term prisoners and the constant introduction of disease into the jails, the indications for prophylaxis are clear. In the diseases that concern us chiefly, the sick man, his excreta and his immediate surroundings are the main foci of infection, the danger being enhanced in institutions by the aggregation of susceptible individuals, and by their common use of dormitories and factories, of vessels, clothing, &c. The practical measures indicated may then be summarised briefly as follows.

Preventive measures.—Prevention of the introduction of infection from outside, by careful examination and observation of all on admission, and the use of observation cells in doubtful and suspicious cases to obviate the danger of association with the community. Prompt recognition of all cases of sickness, or the prodromata thereof, at the first examination and at subsequent parades, to remove sources of infection and for treatment. The utmost practicable isolation of the sick as regards both immediate and mediate communications; with this, observation of recent contacts. Disinfection and careful disposal of all infectious excreta,* of clothing, vessels, wards, latrines, &c. Lastly, surveillance of convalescents till they are fit to rejoin the community without danger thereto. All available resources should be utilized to avoid the congregation of convalescents from different infectious diseases.

That these principles are recognized and largely applied is plain from the records; a specific example is furnished by the success which has attended the efforts to exclude plague from, and suppress it within, the jails during the last six years, and precisely the same measures apply to the other infections in varying degree. With all the provinces affected in 1903 and a recorded mortality of 865,578 among the free population, the cases discovered in the jails numbered 34, of which 23 proved fatal. Of the total number of jails, 245, no less than 159 were situated in infected towns or districts, and of these only 14 returned cases of the disease, eight jails recording only one case each. At the same time, indications are not wanting that there is still room for improvement in the application of these measures to some other prominent infections, as, for example, to tuberculosis.

Thus, an analysis of the 294 fatal cases of tubercle of the lungs which occurred among convicts in India during 1903, discloses the fact that the average duration of illness in each case, from its recognition until death, was just under 70 days. This is certainly not due to a large proportion of acute miliary cases; the case histories rather exhibit a tendency to the recognition of the disease only in its more advanced stages. Over 41 per cent. of these cases were admitted to jail in good or fair health (good, 38 per cent.), 34 per cent. in indifferent, and 24 per cent. in bad health, and in the majority of the latter categories, phthisis was not recognised as present at the time. Thirty per cent. of the deaths occurred among prisoners who had not completed six months' detention; at the same time, the effect of incarceration may possibly be traced in the death-rates, which were 2·6, 3·7 and 5·8 per 1,000 for short, middle and long-term prisoners, respectively. Much has been done, and is being done, for the segregation of these cases and their treatment on modern open-air principles. But if we are to advance on the lines indicated in respect of all infectious disease, we must look to a development of our resources, *e.g.*, the provision of more isolation wards, with self-contained equipment, and, perhaps, of disinfecting apparatus, for the central jails, in the first instance. It remains, before leaving this question of the control of disease, to note a few points of a general character that demand attention.

The problem emerges clearly when the fact is grasped that of the 2,175 deaths among prisoners in 1903, 859 (40 per cent.) were due to diseases of the lungs, including tuberculosis; 260 (12 per cent.) to the specific fevers including malaria; and 638 (29 per cent.) to specific bowel and liver complaints; total 1,757 or 81 per cent. In all three categories, air-space and effective ventilation are the cardinal indications.

---

* Preferably, destruction by fire wherever possible, and noting, in connection with the habits of natives, the infective character of the nasal, pharyngeal, and bronchial excreta, in tubercle, pneumonia, cerebro-spinal fever, leprosy, syphilis, influenza, pneumonic plague, measles and mumps.

Overcrowding and accommodation.—With the growth of the jail population, the necessity arises for an increase and improvement of the accommodation; the average strength disguises the fluctuations of the population, and local and temporary overcrowding, which must occur, presents a problem which is recognized and is partly solved by administrative measures. It is specially as regards convicts that difficulties arise, and chiefly in the provinces of Bombay and Bengal; the circumstances of the former have been very adverse during the past septennium, but in only two of the last 21 years has the present nominal accommodation been in excess of the average strength. In Bengal the most pressing problem, perhaps, is to escape from the arrangement which prevails in many of the dormitories, whereby more than two rows of berths are placed between the ventilation apertures in the opposed walls; this applies to one or several wards of no less than 24 of the 48 jails in the province, and the local authorities are fully alive to the need for reform.

Water supplies.—In the matter of water supply a most satisfactory advance has been made during recent years, in all that concerns the selection of sources and their conservancy. What still remains to be effected in a large number of jails, unprovided with good municipal filtered supplies and which depend on the ground water, is the provision of securer means of raising, of storage, and of distribution, commencing with the pump and the closed well and ending with taps at the necessary points. With this goes also the exclusion of all unauthorised sources from access by the prisoner.

Diet.—And, thirdly, in the same connection, some allusion must be made to the question of diet, a complete discussion of which would greatly exceed the limits of available space on this occasion. That the standard rations are more than ample in amount and excellent in quality is beyond doubt, as proved by a calculation of their theoretical values and by experience; in the year now under review 60 per cent. of the prisoners discharged had gained weight, 16 per cent. only had lost weight. But that 40 per cent. derived no advantage in view of the very large excess of theoretical food-value supplied over the standard laid down by the best authorities, raises the question of the justification of this excess, and its general adaptability to the needs of all classes of prisoners, *e.g.*, to non-labouring prisoners, to those on light labour and to all during the first few months of detention. It is significant that dysentery and diarrhœa, which claim so many victims, are fatal to prisoners in inverse relation to the length of their incarceration. Fifty-six per cent. of the mortality in 1903 fell upon those who had served a term of six months or less, *i.e.*, on 40 per cent. of the average strength; 32 per cent. of the mortality was incurred by those detained from six months to two years, or 37 per cent. of strength; and 12 per cent. by the rest, or 23 per cent. of the strength. Part of the excessive incidence on the first period was due to the condition of prisoners on admission, but 112 of the cases were admitted in good health, 126 in indifferent, and 113 in bad health. Without entering here upon a technical discussion of the relative proportions of the food elements provided in the dietaries, a question which is receiving attention, it may be noted that convicts sentenced to labour receive on the average about 20 ounces of carbohydrate, while those undergoing simple inprisonment obtain 17 ounces, which amounts yield theoretical values of 2,300 and 1,980 kilo-calories, respectively. This is altogether apart from the supply of proteid, which exceeds the standard, and that of fat which may be deemed scarcely sufficient. It has to be noted that the majority of our prisoners are suddenly withdrawn from life and labour in the open air, where starchy food can be disposed of more or less adequately; and further, that the standard of body weight, at 110 lbs. is only three-fourths of that of the European, for whom the best authorities lay down a supply of carbohydrate of 17½ ozs. (kilo-calories, 2,050) for ordinary labour. While taking the different climatic conditions into account and the inevitable waste that is involved in the use of a cereal and vegetable diet, it must still be apparent that waste will not be amended, but rather augmented, by an undue excess of an element, which is the least digestible in the form provided, both by the method of cooking employed and by the amount of cellulose it contains. It can scarcely be doubted that an undue strain is placed upon the intestines and the lungs, and further, that acid fermentation is set up which interferes with the due absorption of proteid, the loss of which is detrimental to the function of the tissues in resistance to disease. The case is not one, however, for arbitrary decision off-hand, but for consideration and

careful study; here, as in other matters, it is necessary to revise our procedure in the light of experience and modern knowledge. For the rest, progress will be the fruit of careful adaptation of measures to circumstances, and an intelligent devotion to details. A brief account may now be given of the conditions prevailing in the different administrations in 1903, and the usual details will be found in the tables in the appendix.

* Excluding subsidiary jails.

† The quinquennial and decennial ratios are, of course, worked on the total strength of the five-year and ten-year periods respectively.

‡ Including Ajmer, Quetta, Mercara, and Secunderabad.

(*a*) Including Berar.

Burma.—Although there was an increase in the number of admissions of all classes of prisoners, the daily average strength was lower than in 1902; in this respect there has been a steady decline during the past five years. The ratios of admission to hospital and of daily sick were the lowest on record, but the death-rate rose to 17·07 per 1,000 from 15·88 in the previous year. This is accounted for by the increased mortality from cholera, pneumonia, dysentery and diarrhœa, enteric fever, and anæmia and debility. On the other hand, it is satisfactory to note a decrease in the prevalence and fatality of tuberculosis for which there were 88 admissions and 39 deaths against 121 and 46, respectively, in 1902. Of the total number, 60 cases, of which 25 were fatal, occurred in central jails, but in 15 of the 32 jails no case was recorded. There were 8 cases of enteric fever, of which 7 proved fatal; a case mortality which would seem to suggest that non-fatal cases escape diagnosis, but the number is too small for any decisive inference. The highest death-rates occurred in some of the smaller district jails, where the average strength is low and a few deaths give a high ratio. On the other hand, the aggregate death-rate in the central jails accommodating over three-fifths of the population, amounted to only 14 per 1,000, the only considerable mortality occurring in Mandalay (30·13), and here 10 of the 21 fatalities were ascribed to dysentery, for which the water supply is held responsible. It has been derived hitherto from a moat subject to pollution, and every endeavour has been made to render it innocuous by boiling and filtering. This has now been excluded from use, and a reputed good and wholesome supply obtained from an artesian well. One further comment may be made on a satisfactory report: a perusal of column 18 in Statement A, in the Appendix of the Provincial Report would appear to show that in many of the jails the site area is unduly restricted; this is an important matter which deserves attention.

Assam.—With a slight rise in the total number of prisoners admitted there was a decrease in the average strength, and the ratios of admission to hospital and of constantly sick were the lowest on record; the death-rate was, however, about the same as in 1902, viz., 31·75 per 1,000 against 31·97, the mean for 1896-1900 being 44·24. There were altogether 36 deaths recorded in 1903, of which 33 occurred in three jails, Tezpur (14), Gauhati (10) and Sylhet (9), in which three-fourths of the average strength were confined, and the marked feature of the mortality was the high rates from bowel complaints, dysentery and diarrhœa, accounting for 18, and cholera for 3 deaths. To the former number Tezpur contributed 11 deaths, and to the latter, one, and with an average strength of 210, the total death-rate in this jail was 66·67. While giving due weight to the condition in which prisoners are admitted, there can be little doubt that this record, which places the Assam jails in an unenviable and unapproached position at the head of the list of mortality from bowel complaints, is a subject for concern, and for reform in regard to all preventive measures. The death-rate in Sylhet, the largest jail, fell from 31·89 in 1902 to 21·74 including one death only from dysentery and one from cholera; this is so far satisfactory, but one can scarcely say it represents what is described as a state of "extreme healthiness," when in addition to the deaths taken into account, it is said that five cases were discharged from jail on account of serious sickness.

Bengal.—There was a decrease in the daily average strength amounting to 2,161 as compared with 1902, but this did not preclude overcrowding, from time to time, in many of the jails; even where the authorized number was not exceeded, the dormitory arrangements frequently involved all the results of overcrowding; it is also doubtful if the site area in many cases be not dangerously restricted. The ratio of admissions to hospital was very slightly higher, of the daily average sick distinctly lower, than in the previous year, while the death-rate fell from 25·61 to 23·62; the rate for convicts in the central jails, accommodating more than half the total population, was only 17·5 per 1,000. This was due to a general improvement as regards all causes of sickness and mortality save tubercle of the lungs and cholera, which show an increase of 12 and 6 fatal cases, respectively. The diminution in prevalence and fatality of dysentery is satisfactory, but it also serves to direct attention to a few jails, where this scourge of the free population of Bengal found favouring conditions, which the authorities recognize and are concerned to reform. The increase of tuberculosis furnishes support to the Inspector General's criticism of the accommodation in barracks and on the site, for those accustomed to work in the open air and whose dwellings have the qualities of their defects of

perviousness. Among the convicts the death-rate from this cause was 4·8, which is exceeded by the Andamans only; in central jails the rate was 5·5; and in district jails 4·2, an advantage determined probably by the shorter terms of confinement in the latter; segregation and open-air treatment are being carried out as far as circumstances permit, but early diagnosis is essential. In the same connexion it may be noted that the pneumonia death-rate shows but little sign of improvement during the last few years. Cerebro-spinal meningitis, which has been a feature of the returns from Bhagalpur in recent years, is said to have "practically disappeared," there having been only two cases and one death in 1903. There were 17 cases of plague, with 12 deaths, and it is noted (and this applies to so many other infectious diseases) that means for enforcing "quarantine" do not exist in most jails, and this necessitates the erection of temporary huts, a costly and insecure expedient.

United Provinces.—There was a notable decrease in the average population in confinement, amounting to 4,610 as compared with 1902, of nearly 7,000 as compared with 1900. Overcrowding was practically obviated, and this also had the result of largely decreasing the number of transfers between jails. The ratios of admissions to hospital and of constantly sick were much below the average, and the death-rate, 15·5 against 20·47 in the previous year, was the lowest on record for the Province, and for India in 1903, if the small North-West Frontier Province be excepted, from which the same rate was returned. There was a decrease in the prevalence and fatality of most of the chief disease causes, and notably of tuberculosis and dysentery and diarrhœa, perhaps the best testimony to the success of the administration and executive, when the very considerable rise in the mortality of the free population is considered. Among the convicts in the central jails, which accommodated nearly half the total average strength, the death-rate was only 12·9 per 1,000, and this falls to 10 per 1,000, if one jail, Agra, be excluded, in which an unusual outbreak of cholera occurred. In some of the district jails where the results were less brilliant, there is a constant reference to the introduction of disease from without, and this should serve to point the application of the remarks made in a former part of this report; the exemplary success obtained in these provinces is, indeed, largely the result of the measures set forth, together with the increased accommodation rendered available by the diminished population.

Punjab.—The daily average strength of all classes of prisoners was slightly lower than in 1902, and there was no notable overcrowding save in three jails, of which two were central. It is said that under no circumstances are dormitories overcrowded, "but the margin of accommodation is far short of what it ought to be." The ventilation of the dormitories and cells in several of the larger jails has recently been improved, and there is ample evidence in every direction of constant progress in the amelioration of the hygienic conditions, and no province can show comparable results in the steady decline of mortality during the last quarter of a century. In 1903 the ratios of admissions and constantly sick were well below the average, and the death-rate fell from 25·04 per 1,000 in 1902 to 19·16, while that of the free population rose from 44 to 49 per 1,000. With cholera and plague widely prevalent outside, there were only two deaths from the former and one from the latter in the jails during the year, but it is remarked that the arrangements for the disinfection of clothing and bedding, the contamination of which promotes the spread of all forms of infectious disease, are far from satisfactory. All the chief causes of sickness and mortality were less prevalent and less fatal, although certain jails are subject beyond others to the occurrence of pneumonia and of tuberculosis, about half the total mortality from the former being reported from 5 of the largest district jails holding one-fourth of the total strength, while 23 deaths out of 38 from the latter cause occurred in three central jails, accommodating a little more than one-third of the population. The decline in the rates from dysentery and diarrhœa taken together is a very satisfactory feature of the year's work, the mortality in the last three years yielding ratios of 5·7, 3·9 and 2·6 per 1,000 respectively.

North-West Frontier Province.—There was a daily average strength of only 1,280 prisoners of all classes, confined in the five jails of this area during the year, a slight increase on the number for 1902. There was overcrowding at Bannu and Kohat for nearly half the year, and at Abbottabad and Peshawar it was also noticeable; this necessitated the accommodation of the excess in tents, in workshops, in the hospital verandahs and cook-house, which is most undesirable. Nevertheless,

the general health of the prisoners was good, for, with an insignificant rise in the sickness rate, there was a fall in the death-rate from 29·46 to 15·54. There was a decrease in the admissions from all causes save malaria, which was specially prevalent at Dera Ismail Khan, and the mortality calls for no special comment.

Bombay.—There was a great extension of the plague epidemic among the free population which in other respects was somewhat better off both as regards general health, and material circumstances, owing to good harvests and lower food prices. The average strength of prisoners of all classes was less by about 2,000 than in 1902, and yet of the 14 jails (excluding the "gangs") in the Presidency and Sind, 10 were overcroweded throughout the year, and one more was subject to temporary overcrowding. This is a serious situation, not of a temporary or accidental nature; it is a standing disability which is bound to leave its mark on the vital statistics, inasmuch as all preventive measures operate at a disadvantage. The record for the year under review presents, however, many signs of improvement; the ratios of admissions to hospital and of constantly sick fell to a point which is very low when the death-rate is considered, viz., 26·41 against 28·89 in the previous year, and this is attributed to the better condition of prisoners on admission and to the decrease in their numbers. There was less sickness under most of the main heads save respiratory diseases, less mortality from all causes save pneumonia. As is to be expected under the conditions prevailing, diseases of the lungs are more frequent and fatal here than elsewhere; while the mortality rate for India as a whole from tuberculosis, pneumonia and other lung diseases combined is 7·3, it rises to 13·07 in Bombay, due to the excess returned under the latter two heads. Among the convicts in Sind, with an average strength of 1,617, there were 90 deaths (a rate of 55·6 per 1,000) of which 59 were due to these causes, and 49 to pneumonia alone, to which last the small Sind gang contributed 33. The ventilation of the barracks which have roofs of reed mats is said to be good, but the space area per man is only 28 square feet and 280 cubic feet, and it is difficult to see how ventilation in the winter (in Sind) can be adequate without involving dangerous draught. Moreover, the men were locked up earlier at night and the barracks evacuated later next morning to avoid the cold and, with it, the fresh air. The first essential in the prevention of pneumonia is ample ventilation, and for this, ample space; and with adequate clothing the temperature of the air may be disregarded. The two prisons in Bombay City are structurally very defective and were badly overcrowded; the combined death-rate of the native convicts amounted to 56·6 per 1,000, but as the matter is understood to be receiving the attention of the Local Government, any further discussion of it may be deferred.

Central Provinces.—Berar having been incorporated administratively with this area, the jail statistics of both will henceforth be discussed under this heading. The recovery of the people from the results of famine is plainly marked in the great diminution of crime, the daily average strength of all classes of prisoners fell in 1903 to less than half the number confined during the famine (1897), to a point below the lowest previously on record. In spite of this there was overcrowding of convicts, more or less temporary, in five of the jails, and additional accommodation is required for prisoners under trial. The improvement in the health of the prisoners was marked both in regard to sickness and mortality, and this is the case in respect of nearly all the main causes of disease. The death-rate for the period 1896-1900 was 66·18, falling to 23·55 in 1902, and again to 18·16 in the year under review, and this with a rise of about 8 per 1,000 in the death-rate among the free population. This happy result is largely due to the diminished mortality among convicts reported from Jubbulpur Central Jail, though Nagpur Central and the District Jails, as a whole, also show to advantage, if in less degree, having less leeway to recover. The success which attended the exclusion of plague from the jails was equally satisfactory; although the disease was epidemic in 12 headquarter towns, only three cases with one death were recorded among the prisoners.

Madras.—A prosperous year for the people at large resulted in a great decrease in the number of prisoners admitted, and the average strength of all classes confined fell by over 1,500 below the number in 1902. The accommodation in only three of the jails was found insufficient for the local demands, and the disability was reduced by transfers. The general health of the prisoners was very good as shown by the

hospital admission and constantly sick-rates, and far below the average both for the Presidency and for India as a whole. The death-rate amounted to 19·20 per 1,000 against 18·49 in 1902, and 28·3, the mean for the quinquennium 1896-1900, the slight rise over that of the previous year being due to cholera which accounted for 11 deaths (against 3 in 1902), 7 of which occurred in one jail, Berhampur. There is little that calls for comment in this favourable record save to remark the extraordinarily low death-rate from dysentery to which the convicts, in the central jails especially, were subject. In these institutions 65 per cent. of the total convict population is confined, and the mortality from dysentery in 1903 amounted to only 1·7 per 1,000 of strength against 3·73 for India as a whole. At the same time the death-rate from diarrhœa is just over double the average elsewhere, so that if the rates are combined, there is little variation from the mean. The post-mortem records support the view that the term "dysentery" is used in a restricted sense in Madras, when compared with the usage elsewhere, and that the lower death-rate does not connote any special immunity to a form of disease which often presents difficulties to exact discrimination. The relative immunity of the large jails of Rajahmundry and Cannanore to all forms of bowel complaints is exceedingly creditable to the officers, or officer, concerned.

Andamans.—In 1903 rain fell to the amount of 116 inches, about the average of the previous lustrum, but fully 22 inches below the total for 1902; it fell on 181 days out of the 245 from May to December, *i.e.*, on three days out of four during eight months. A steady increase in the convict population is to be noted during the last nine years, the average strength during 1896-1900 was 10,975, rising to 12,907 in 1902, and to 13,037 in 1903; the large decrease in crime and in the jail population in India had not yet affected the Settlement. "Many of the barracks are now filled to their utmost capacity"; the local Jail Manual provides for a maximum allowance of cubic space per unit (648 cubic feet), but this appears to be rarely or never attained, and the minimum is uncertain, the only standard maintained being that of floor space (36 square feet), and yet the convicts are aggregated in four rows in the dormitories, an arrangement which renders efficient ventilation incompatible with exclusion of rain. The increase in recent years of the criminal population of the Andamans has not been met by a corresponding increase of accommodation, but improvements in this direction and in the food and water supplies are in progress.

The ratios of admissions to hospital and of constantly sick have been recently nearly twice as high as those prevailing among convicts in India, and the mortality rates for the past three quinquennia were 38·5, 27·8 and 39·08 per 1,000 respectively. In 1903 the ratios are: admissions to hospital, 1,880; constantly sick, 67; deaths, 34·21; against 1,797, 56 and 42·07 per 1,000 respectively, in 1902. But if a distinction is made between "self-supporting" and "labouring" convicts, with an average strength of about 2,000 of the former to 11,000 of the latter, it is found that, on the average of the past 5 years the constantly sick-rate was fully 8 times and the death-rate nearly two and a half times greater among the latter class, or, as 66 to 8, and as 41 to 17. As regards sickness, malarial fevers account for about 60 per cent. of the total, bowel complaints for 11 to 12 per cent., and respiratory disorders including phthisis for 6 to 7 per cent.; the mortality falling in reverse order, lung diseases yielding 40 to 45 per cent., bowel complaints 30 to 40 per cent., and malaria 7 to 11 per cent. of the total. The problems which this bare statement discloses have recently received detailed study by the medical officers on the spot, and if the measures proposed could be carried out consistently in their entirety, and with adequate authority and resources, there can be little doubt of the results. These measures were summarised in the report furnished last year, and the hope may be expressed that their effects are visible in the reduction of the mortality from malarial fevers and dysentery to nearly one-half of the amount of the previous year, while there have been 17 less deaths from respiratory diseases, including 14 from pulmonary phthisis—184 against 201. This is decidedly encouraging to sustained and strenuous efforts, even if the desired end tarry, and there are circumstances in the life conditions of the labouring convicts of peculiar difficulty. They are exiles, they are put to unaccustomed labour and exposed to stress of weather, of which some indication has been given; it cannot, therefore, be anticipated that the vital statistics will compare favourably with those of convicts in India. Finally, it would be well to modify the form of the Annual Report on the lines of the Indian Adminis-

trative Reports; many points would receive elucidation that are at present doubtful and unexplained, and every measure that contributes to the marking down of the causes and incidence of sickness will promote the end in view.

Coorg, Rajputana, Baluchistan, Secunderabad.—There was a very considerable improvement in the health statistics of these small jails; in all save that of Secunderabad, the constantly sick-rate was lower than in the previous year, but here and in the Quetta jail there were no deaths recorded in 1903. At Ajmer the death-rate per 1,000 of an average strength of 420 was only 7·14 against 29·57 in 1902, and at Mercara it was 13·89, or just about one-third of the previous year's rate. These fluctuations call for no comment as they are inevitable in the case of institutions the average strength of the inmates of which does not amount to 100, save in the case of Ajmer.

Epidemic disease.—In conclusion, a few words will suffice to indicate the prevalence of the chief forms of acute epidemic disease to which the jail population was liable during the past year. Cholera was more prevalent among the free population than in 1902, and the returns from the jails show a rise from 36 cases and 24 deaths in that year to 97 and 57, respectively, in 1903. The only considerable outbreaks were in the jails at Berhampur (14 cases), Agra Central (12), and Angul (11), the rest of the cases being distributed among 26 jails, Bengal, Madras, Burma and the United Provinces sharing the largest number. The admission rate for India was 1·0 per 1,000 of strength, and the death-rate ·56, a result which is in accordance with the steady diminution during the last half century. Small-pox was also slightly more prevalent with 62 cases and 6 deaths against 47 and 6, respectively, in 1902; the disease appeared in 30 jails, Dera Ghazi Khan returning 8 cases, Gauhati 6, and Fyzabad 5; the death-rate per 1,000 of total strength was .06, or about the quinquennial average. Influenza caused about the same amount of sickness as in the previous year, 977 cases against 912, with 13 against 16 fatalities, the disease being most prevalent in the Central Provinces, Bengal, Andamans and the United Provinces. The success which attended the exclusion of plague from the jails during the year has been alluded to (page 75). It is also satisfactory to record a marked decrease in the occurrence of cerebro-spinal meningitis, the number of cases and deaths reported during the last three years being 141 and 102, 136 and 108, 34 and 27, in 20, 19 and 14 institutions, respectively. The pathological records scarcely afford conclusive evidence that all these cases were the result of infection by the specific meningo-coccus; influenza, pneumonia and tubercle were, one or more, present in the jails and cannot be excluded from the etiology in some instances. Relapsing fever, which has been a feature of the Bombay returns since the famine, accounted for 102 cases of which 8 proved fatal; all but 7 of the cases, and all the deaths, occurred in the two jails in Bombay city; in the previous year the Presidency returned 218 cases with 4 deaths among the prisoners. The diagnosis of enteric fever was made in 45 cases, of which 25 proved fatal, and on the whole, it is supported by the post-mortem records, and in a few cases confirmed by the Widal and bacteriological tests. The disease appeared in 28 jails, of which 21 had only one case each, a fact which militates against the discovery of its origin, as to which, indeed, medical officers have little unequivocal evidence to offer, and in most cases they are altogether at a loss for a clue, beyond that of some chance fæcal infection. There were 6 cases (2 fatal) of beri-beri in 1903, shared equally between Burma and Assam. Epidemic dropsy was practically confined to one jail, Barisal, which returned 26 cases with 8 deaths, the continuation of an outbreak in the previous year. Lastly, the prevalence of mumps, confined chiefly to Bengal, the Punjab and the United Provinces, showed a decrease from a total of 1,368 cases in 1902 to 449 in the year under review.

The General Population.

Births in India.—In 1903, among the census population of 226,831,150* under registration in the British provinces of India, there were recorded 8,736,652 births, or 54,562 less than in the previous year. The number of births declined in seven provinces, but in Assam, the United Provinces, Madras, Coorg and Lower Burma the numbers increased, the increase being specially remarkable in Madras where a larger number of births were recorded in 1903 than in any previous year. The mean birth-rate of the whole population was 38·96 per 1,000, as compared with 39·38 in 1902, the birth-rates ranging in the various provinces from 46·13 in the United Provinces to 29·48 in Ajmer-Merwara and 26·51 in Coorg. In eight provinces the birth-rate was higher than the death-rate, the excess being greatest in the Central provinces and Berar, 9·59 per 1,000; Lower Burma, 9·41; Assam, 9·02; and Madras, 9·01. In Bombay, where the death-rate attributed to plague was 15·22, the total death-rate exceeded the birth-rate by 12·69 per 1,000; in the Punjab, where the plague death-rate was 10·22, the excess of deaths over births was 6·1 per 1,000; in Coorg, the number of births recorded was very small; and in Upper Burma the registration of births seems to be much more defective than the registration of deaths. The mean percentage of male and female births recorded was 106·6, ranging from 127·7 in Sind and 122·8 in the North-West Frontier Province to 103·9 in Madras.

Deaths in India.—The total number of deaths registered was 7,881,125, or 768,789 more than in 1902. The mean general death-rate was 34·7 per 1,000, as compared with 31·49 in 1902. In Bengal the death-rate was slightly less, and in Assam and Ajmer-Merwara it was considerably less than in 1902; in all the other provinces the death-rates of 1903 were higher than the death-rates of 1902, the excess being greatest in the United Provinces and the Central Provinces. In every province, except Assam, the urban were higher than the rural death-rates, but in Madras, where there was a sudden great improvement in registration in rural areas during the year, the excess was only 2 per 1,000.

The largest number of deaths recorded in one month was 753,663 in November, but in the Central Provinces and Berar alone among the provinces was the maximum mortality recorded in that month. The smallest number of deaths were recorded in the month of February, but this was due to the shortness of the month, for the mean number of deaths recorded in the day was lower in August (18,954) and July (20,276) than in February (20,750). In December the maximum mortality was recorded in Bengal, Assam, the North-West Frontier Province, Ajmer-Merwara and Madras; and in February the minimum mortality was recorded in Assam, the United Provinces, Coorg, Lower Burma and Upper Burma. In January mortality in Bombay was at its highest. In April the maximum mortality was recorded in the Punjab, and the minimum in the North-West Frontier Province. June was the month of highest mortality in the United Provinces, and of lowest mortality in Bombay. July was the month of highest mortality in Lower Burma and Upper Burma, and of lowest mortality in the Central Provinces and Berar and in Ajmer-Merwara. In August occurred the largest number of deaths in Coorg, and the smallest number of deaths in the Punjab. In October the mortality in Bengal was at its lowest.

In the United Provinces, the Punjab, the North-West Frontier Province, Bombay and Ajmer-Merwara the death-rates of females were higher than the death-rates of males, the excess of female mortality being most notable in the Punjab where it amounted to 8·5 per 1,000.

Cholera was most fatal in Bengal (death-rate 2·73 per 1,000), Assam (1·58) and Upper Burma (1·0); and small-pox in the North-West Frontier Province (1·35), the Punjab (·78) and the United Provinces (·46). The highest death-rates from plague occurred in Bombay (15·22), the Punjab (10·22), the Central Provinces and Berar (4·13) and the United Provinces (1·77). Respiratory diseases were most fatal in the provinces which suffered most severely from plague, but the death-rate in the Punjab (3·38) was slightly higher than the rate in Bombay (3·21); the Central Pro-

* The population under registration for births numbers 224,239,195. This is due to the registration of births in Upper Burma being at present limited to 12 towns,

vinces and Berar (1·36) and Ajmer-Merwara (·57) followed, and the rate in the United Provinces (·50) was equalled by the rate in the North-West Frontier Province (·50).

The death-rates from dysentery and diarrhœa were highest in Bombay (3·0), the Central Provinces and Berar (2·66) and Assam (1·99); and the highest rate recorded under fever was in the United Provinces (27·65), where measles was unusually prevalent.

* Excluding Tundla Town. † Not available. ‡ For Central Provinces. Information for Berar not available.
§ Statistics of births for 13 towns only. ‖ Statistics of births for 12 towns only.

In the following paragraphs will be found the principal details of registration in the various provinces.

Bengal.—In 1903 the number of births recorded in the 724 registration circles in Bengal was 2,903,191, or 84,609 fewer than in the preceding year, and the birth-rate of the province was 39·0 per 1,000, as compared with 40·14 in 1902 and a mean quinquennial rate of 38·17. Among the districts the highest birth-rates were 50·91, 47·55 and 47·42 recorded in Gaya, Noakhali and Monghyr, respectively, and the lowest recorded were 30·53 in Howrah, 28·88 in Hooghly and 15·54 in the urban district of Calcutta. In ten of the towns, including Tikari (53·90) in Gaya, Dumka (48·06) in the Sonthal Parganas, and Nawabganj (46·95) in Malda, rates in excess of 40 per 1,000 were recorded, but in no less than eighty-five towns the registered rates were below 25, so that the mean urban rate was only 23·74 as compared with 39·81 in rural areas. The mean percentage of male to female births was 105, ranging in the districts from 112 in Howrah to 101 in Gaya.

The recorded deaths during 1903 aggregated 2,481,149, or 7,279 fewer than in 1902, and the death-rate was 33·33 per 1,000, against 33·43 in the previous year and a mean of 30·92 in the previous five years. Among the districts, the highest

rates were 48·73, 46·77 and 45·98 recorded, respectively, in Saran, Patna and Shahabad, all districts in which plague was prevalent; while the lowest rates were 23·51, 23·41 and 19·30 recorded, respectively, in Tippera, Ranchi and Singhbhum. The mean death-rate of the towns was 36·39 against 33·17 in rural areas. The higher mean rate in the towns was due to the greater prevalence in them of plague; excessive rates such as 78·23 in Revelganj, 76·24 in Patna City and 72·34 in Barh being due to the presence of plague; but the mean urban mortality was largely reduced by the effects of bad registration or peculiar conditions in many towns where the birth-rates also are very low, *e.g.*, Ranchi, death-rate, 9·08; Nasirabad, 8·52; and Jhalakati, 4·96.

Among the different sects, the Hindu death-rate was the highest, 34·55, and the Christian the lowest, 19·07; Muhammadans, 32·06, "other classes," 24·53, and Buddhists, 23·49, occupying intermediate positions.

The death-rates among male and female infants were 203·5 and 185·1 per 1,000 born during the year; and boys and girls between one year and five years of age died at the rate of 50·10 and 44·12, respectively. At all the age periods, except 15-20, the male death-rates were the higher, the male death-rate at all ages being 34·87 against a female rate of 31·80.

Port of Calcutta.—A total of 20,253 European seamen arrived in the Port of Calcutta during 1903, giving a daily average population of 1,145 against 1,154 in 1902. The death-rate in 1903 was less than half that of the preceding year, and considerably lower than the rate in any of the four preceding years. The number of deaths was only 10, including four from cholera, as compared with 23, including 13 from cholera in 1902; the ratio of deaths for the two years were 8·73 and 19·93 per 1,000, respectively.

The total number of deaths in and out of hospitals, during 1903, among the estimated native floating population of 25,630, amounted to 152 against 138 during 1902, the ratios being 5·93 and 5·37 per 1,000, respectively. There were 69 deaths from cholera, but none recorded as due to either small-pox or plague.

Assam.—In Assam the number of births registered in 1903 was 187,669, or 7,194 more than in the preceding year, and the birth-rate was 35·57 per 1,000 against 34·21 in 1902. The highest district birth-rate was as usual registered in Goalpara, 43·22, followed by Sylhet and Darrang, where the birth-rates were 38·16 and 35·26, respectively; the lowest district birth-rates were 33·19 in Kamrup, 28·04 in Lakhimpur and 27·81 in Sibsagar. In rural areas the mean birth-rate was 35·73 per 1,000 as compared with 28·24 in the towns. By far the highest urban rate was 48·45 recorded in Barpeta where alone among Assam towns the female population is greater than the male population. The percentage of male to female births ranged from 111·97 in Sibsagar to 104·81 in Cachar, the mean being 106·72.

The number of deaths recorded was 140,069, or 13,001 fewer than in 1902, the death-rates of the two years being, respectively, 26·55 and 29·01. The highest district death-rate was 38·10, recorded in Darrang, where kala-azar was most prevalent and severe during the year. The next highest death-rates were 33·02 and 27·93 recorded in Gaolpara and Cachar, respectively, while the lowest rates were 22·73 recorded in Kamrup, 22·22 in Lakhimpur and 18·23 in Sibsagar. In rural areas the mean death-rate was 26·56 against 26·17 in the towns, among which the extreme rates were 38·57 in Golaghat and 16·09 in Silchar.

Muhammadans and Hindus died at the rates of 27·64 and 23·34 per 1,000, respectively, while Christians and "other classes" died at the rates of 14·41 and 44·24.

The death-rates among infants were 193·83 and 183·38 per 1,000 males and females born during the year. Boys and girls between the ages of one year and five years died at the rates of 31·51 and 30·54. The male death-rates were higher than those of females at all age periods, except 15-20, 20-30 and 30-40, the general mean being 26·71 among males and 26·38 among females.

Assam Tea Gardens.—The statistics relating to the tea gardens in Assam relate to the year ending the 30th June, 1904, during which the mean annual strength of the coolies employed rose from 644,045 to 654,021. Of this number 39·61 per cent. were employed in the Surma Valley and 60·39 per cent. in the Assam Valley, the distribution approximating closely to that of the preceding year. The birth-rate

was lower than during 1902-3; the recorded figures of that year, 30·8 per 1,000 of the total and 98·6 per 1,000 of the adult female population, having declined to 28·9 and 93·4 per 1,000, respectively, rates which compare unfavourably with the corresponding ratios of 35·37 and 125·0 for the province.

The death-rate fell from 25·4 to 24·0 per 1,000. Of the deaths, which totalled 15,742, malarial fevers caused the largest number (2,493), followed by dysentery (2,445), anchylostomiasis (1,985), respiratory diseases (1,884), diarrhœa (1,624) and cholera (738).

During the journey of the coolies to the Assam Valley, 16 deaths only occurred as compared with 57 in the previous year, 10 against 42 being due to cholera. No death occurred among coolies in transit to the Surma Valley or at the depôts of the Sylhet and Cachar districts.

United Provinces.—The number of births registered in the United Provinces in 1903 was 2,200,031 against 2,186,201 in the preceding year, and the birth-rate was 46·13 per 1,000 as compared with 45·84 in 1902 and a quinquennial mean of 42·60. In eleven districts, headed by Shahjehanpur 56·08, Hardoi 55·68, and Budaun 55·24, the birth-rates were above 50 per 1,000, and in only two, Naini Tal 31·36 and Dehra Dun 28·49, were they below 35. The mean birth-rate in towns was 42·88, the rates ranging from 64·73 in Pihani to 23·21 in Mirzapur-Bindhachal, 16·57 in Naini Tal and 12·87 in Mussoorie. The percentage of male to female births ranged from 113·24 in Ballia to 103·20 in Benares, the provincial mean being 107·59 against 107·25 in 1902.

The number of deaths recorded was 1,920,903 against 1,552,046 in 1902, and the death-rate was 40·28 as compared with 32·54 in 1902 and a quinquennial mean of 30·91. The highest district rates were 55·90 in Hamirpur, recorded mainly as fevers and other causes, and 54·14 and 52·11 in Lucknow and Cawnpore, both districts in which plague was severe. The mean rural death-rate was 39·16 against 54·86 in the towns, in many of which, including Cawnpore 89·47, Sahatwar 81·4, Sitapur 78·35, Nawabganj 75·01 and Fyzabad-Ajodhya 71·71, plague was severely epidemic. The second highest municipal death-rate was recorded in Hardwar, where a death-rate of 81·73 per 1,000 includes rates of 8·32 under cholera, 2·97 under plague, 48·91 under fevers and 5·90 under dysentery and diarrhœa.

The death-rate among Christians was 12·00, among Muhammadans 41·01, and among Hindus 39·85, the last rate being reduced artificially by the inclusion of the deaths of certain sects of Hindus among "other classes."

Owing to the prevalence of measles the death-rates of children were very high, 279·2 male and 269·1 female infants, respectively, having died among every thousand born, while boys and girls between the ages of one year and five years died at the rates of 89·71 and 88·49 per 1,000 living, according to the census figures. In the age periods 10-15, 15-20, 20-30 and 30-40 the female death-rates were higher than the male, the excess being most marked in the age period 15-20. The mean death-rates were among males 40·15, among females 40·41.

Punjab.—The number of births recorded in the Punjab fell from 880,477 in 1902 to 862,862 in 1903, the birth-rate in the latter year being 42·9 against 43·8 in 1902 and a quinquennial mean of 40·7. Among the districts the highest birth-rates were 50·1, 49·7 and 46·7 recorded, respectively, in Sialkot, Jhang and Mooltan; and the lowest 35·0, 34·5 and 17·3 in Kangra, Dera Ghazi Khan and Simla, respectively. The mean percentage of male to female births was 110·3, the percentages ranging in the districts from 121·8 in Dera Ghazi Khan to 104·6 in Delhi.

While the number of births recorded in 1903 was considerably less than in 1902, the number of deaths was much greater, the figure rising from 886,973 in the earlier to 985,476 in the later year. The death-rate in 1903 was 49·0 per 1,000 against 44·1 in 1902 and a quinquennial mean of 36·7. Among the districts the highest death-rates were 96·3 recorded in Gujranwala, where the plague death-rate was 63 per 1,000, 74·9 in Amritsar, where the plague and fever death-rates were, respectively, 25·6 and 32·2 per 1,000, and 66·1 in Jullundur, where the plague death-rate was 28·6; and the lowest, 26·6 in Montgomery, 26·3 in Dera Ghazi Khan and 24·5 in Simla. In rural areas the mean death-rate was 48·58 as compared with 52·89 in the towns, in some of which enormous rates due to deaths registered under the headings plague or fever were recorded. Muhammadans died at the rate of 49·36 per 1,000, and Hindus at the rate of 48·68; Christians died at the rate of 23·90, and "other classes,"

to whom the deaths of many persons placed under other headings at the census are credited, at the recorded rate of 64·57.

The death-rates of male and female infants estimated on the number of births recorded during the year were 260 and 270 per 1,000, respectively, the female death-rate being considerably the higher. Boys and girls over one year and under five years of age died at the rates of 72·48 and 80·17, respectively, and at all age-periods the female death-rates were the higher, the provincial means being 45·1 among males and 53·6 among females.

North-West Frontier Province.—The number of births registered in 1903 was 62,866, or 4,038 fewer than in 1902, and the birth-rate which was 33·6 in the earlier year fell to 31·6 in the later year, the rates in the district ranging from 56·2 in Dera Ismail Khan to 29·7 in Peshawar. The provincial mean percentage of male and female births rose from 121·9 in 1902 to 122·8 in 1903, ranging from 136·0 in Peshawar to 109·1 in Hazara.

The number of recorded deaths, which in 1902 was 48,624, increased by 7,915 to 56,539 in 1903, and the death-rate rose from 24·4 per 1,000 to 28·4, ranging in the districts from 35·8 in Dera Ismail Khan to 22·9 in Hazara. In rural areas the death-rate averaged 28·0 against 32·8 in the towns, in some of which high rates, mainly due to fevers, were recorded. Muhammadans died at the rate of 28·93 per 1,000, Hindus at the rate of 23·70 and Christians and "other classes" at the rates of 8·28 and 13·49, respectively. For every thousand births recorded of males there were recorded 202·9 deaths of male infants, the corresponding figure for females being 198·8. Boys and girls between one year and five years of age died at the rates of 56·60 and 58·05, respectively. At all age periods, except 50-60, the female death-rates were the higher, the mean total rates being 27·6 among males and 29·4 among females.

Central Provinces and Berar.—Consequent upon the union of Berar with the Central Provinces, the sanitary administration of the former was taken over by the Sanitary Commissioner of the Central Provinces on November 1st, 1903, and in future the statistics of the Provinces will be treated together. In 1903 there were 432,491 and 131,057 births recorded in the Central Provinces and Berar, respectively, the birth-rates being 44·27 and 48·16 against 48·29 and 56·9, respectively, in the preceding year. Calculating the total births recorded, 563,548, on the aggregate population of the two provinces, the birth-rate was 45·11 per 1,000 compared with a birth-rate similarly calculated for 1902 of 50·17. Among the districts the highest rates were 52·09 in Mandla, 51·39 in Wun and 50·38 in Wardha; and the lowest 39·80 in Raipur, 38·82 in Bhandara and 37·41 in Burhanpur, in which plague was particularly severe. The rural birth-rate was 44·90 as compared with 37·25 in the towns in the Central Provinces; the corresponding figures for Berar were 49·42 and 41·15, respectively. The percentage of male to female births was 104·97 in the province as a whole; in the Central Provinces it was 104·90, ranging from 108·91 in Damoh to 103·00 in Mandla; in Berar it was 105·22, ranging between 106·74 in Ellichpur to 103·96 in Wun.

The total number of deaths recorded was 443,697, including 330,104 in the Central Provinces and 113,593 in Berar. The total death-rate was 35·52 as compared with 27·33 in 1902; the death-rate of the Central Provinces being 33·79 per 1,000 against 25·82 in the preceding year; and that of Berar 41·74 against 32·80. Among the districts, the highest rates were recorded in Burhanpur, 65·31, including 21·95 from plague, Nagpur 58·33, including 20·34 from plague, and Narsingpur 55·34, including 8·15 from plague; the lowest in Balaghat (23·62), and Bhandara (22·66), in both of which plague was comparatively slight, and Sambalpur (20·02), from which plague was entirely absent. In rural areas the mean death-rate was 32·36 as compared with 64·59 in the towns. Among the latter excessively high rates were registered in Kamptee, 166·04, of which 108·11 was due to the occurrence of 4,202 deaths from plague; Amraoti, 129·35, of which 93·12 was due to plague; Nagpur, 115·90 (plague 75·17); and Murtizapur, 100·39 (plague 62·86). Muhammadans and "other classes" died at the rate of 52·69 and 52·47 per 1,000, respectively, and Hindus at the rate of 32·23.

Male infants died at the rate of 285·1 per 1,000 born, and females at the rate of 257·0. Boys and girls over one year and under five years died at the rates of 53·80 and 47·05, respectively. The female death-rates were very slightly higher than the male rates in the age periods 10-15 and 15-20, the mean rates at all ages being 37·18 among males and 33·89 among females.

Madras.—There were 1,165,080 births registered in Madras in 1903, the highest number yet recorded, equal to a birth-rate of 31·2 per 1,000 as compared with 28·2 in 1902 and a quinquennial mean of 28·8. The highest district birth-rates were 39·2 in Chingleput, 39·0 in Madras and 34·3 in both Tanjore and Tinnevelly; the lowest rates were 28·0 in Cuddapah, 24·8 in Ganjam and 23·3 in Madura. The mean birth-rate recorded in the rural areas was 31·2 against 31·4 in the towns. By far the highest urban rate was 87·6 recorded in Sermadevi, a town of about 13,500 inhabitants, in Tinnevelly, followed by rate of 50·2 in Vaniyambadi, and 48·4 in Kadayanallur. At the other end of the scale were Nellikuppam, a town of 13,137 inhabitants, in South Arcot, where the recorded birth-rate was 3 per 1,000, Vempalli (population 10,793) in Cuddapah, where the rate was 1·7, and Vetapalemu in Kistna, where the rate was 1·2. The percentage of male and female births ranged from 106·8 in Ganjam to 100·3 in Anantapur, the provisional mean being 103·6.

The recorded deaths numbered 826,663 or 94,226 more than in 1902, and the registered death-rate rose from 20·2 in that year to 22·2 in 1903, which is 1 per 1,000 more than the quinquennial mean. In the districts the rates ranged from 37·9 in Madras to 18·1 in Vizagapatan, 16·1 in Madura and 14·6 in Ganjam. In rural areas the mean death-rate was 21·5 as compared with 27·3 in the towns. Among the latter the enormous rate of 162·4 was registered in Vaniyambadi (population 12,005), where a death-rate from plague of 113·7 per 1,000 coincided with a birth-rate of over 50. The next highest death-rate was 56·3 recorded in Tiruppattura, where the plague death-rate was 33·0, and this was followed by a rate of 44·7 in Coonoor, including 14·2 ascribed to plague. In Rajampet, a town of over 15,000 inhabitants, in Cuddapah, the death-rate was reported to be 2·7, and in Vempalli and Vetapalemu, respectively, the recorded death-rates were 1·9 and ·5 per 1,000.

Muhammadans, Hindus and Christians died at the rates of 24·5, 22·3 and 19·4, respectively.

Male infants died at the rate of 186·7 and female infants at the rate of 168·2 per 1,000 born during the year, respectively; and boys and girls over one year and under five years of age died at the rates of 30·1 and 28·6. In the three age periods between 10 and 30, the female death-rates were the higher, the general rates for the sexes being 22·8 among males and 21·5 among females.

Coorg.—The number of births registered in Coorg was 4,787 or 468 more than in 1902, and the birth-rate rose from 23·91 in that year to 26·51 in 1903, ranging in the districts from 39·10 in Padinalknad to 18·70 in Yedenalknad. The percentage of male and female births was 104·31.

The total number of deaths rose from 4,887 in 1902 to 5,676 in 1903, and the death-rate from 27·06 to 31·43, ranging in the districts from 36·02 in Nanjarajapatna to 29·0 in Kiggatnad. In rural areas the mean death-rate was 29·82 against a town rate of 48·79. By far the highest town death-rate was 83·12 recorded in Virajendrapet, where the mortality from dysentery and diarrhœa was 16·58, from plague 6.30 and from "other causes" 32·92. The death-rate of Muhammadans was 36·99, those of Hindus and "other classes" 30·97 and 30·11, respectively. The death-rates of male and female infants were 253·7 and 198·5, respectively, per 1,000 born; and of boys and girls between the ages of one year and five years 40·83 and 32·93. In the age periods 15-20, 20-30 and 30-40 the female death-rates were the higher, the means at all ages being 30·78 and 32·23.

Bombay.—The births recorded in the presidency of Bombay during 1903 numbered only 576,949 as compared with 631,393 in 1902 and 664,305 in 1893. The birth-rate, which had risen from 25·19 per 1,000 in 1901 to 34·16 in 1902, fell to 31·22 in 1903. Among the districts the highest rates were registered in Ahmednagar 43·30, Khandesh 42·64 and Nasik 40·18, and the lowest in the City of Bombay 21·19, and in the Sind districts of Hyderabad 17·61, and Thar and Parkar 13·25. In rural areas the mean rate was 32·37 as compared with 23·56 in the towns. The percentage of male to female births in the presidency as a whole was 107·94, ranging in the districts of Bombay proper from 108·41 in Bombay City and 108·29 in Kaira to 101·15 in Bijapur, and in the districts of Sind from 138·24 in Hyderabad to 116·98 in Karachi.

The registered deaths numbered 811,525, the highest number on record except that recorded in 1900, when the deaths numbered 1,318,783. The death-rate in 1903, which includes a death-rate of 15·22 ascribed to plague, was 43·91, or 4·87 per

1,000 higher than in the preceding year. In the districts of Belgaum and Dharwar, where plague was most severe, the recorded death-rates were, respectively, 74·53 and 73·93 per 1,000; in the City of Bombay the death-rate was 65·99, and in the district of Sholapur 64·94. Of the six districts in Sind, where registration is most defective, some were free from plague, and in two of those, Thar and Parkar, 17·95, and Upper Sind Frontier, 15·19, the lowest death-rates were registered. In rural areas the mean death-rate was 41·51 against 18·36 in the towns, among which the mean plague death-rate was 23·89 as compared with 13·19 in rural areas. Among the towns by far the highest rates were recorded in Athni (138·83), a town of 11,107 inhabitants, in the Belgaum district, where 1,165 plague deaths were reported, and Ranebennur (123·90), a town of 14,851 inhabitants, in the Dharwar district, where the plague deaths numbered 1,379. In Ahmednagar the death-rate was 84·45, including rates of 42·23 recorded under plague and 15·54 under respiratory diseases. The lowest rates were 18·36 in Karwar and 14·20 in Vengurla, in each of which only one plague death was reported.

The death-rate of Hindus was 47·70, against rates of 30·65 among Muhammadans, 27·60 among Christians and 27·11 among Parsis.

The death-rate among male infants was 219·57 and among female infants 206·70 per 1,000 born, respectively; and boys and girls between the ages of one year and five years died at the rates of 53·29 and 51·26. In infancy, childhood, and from middle age onwards, the male death-rates were the higher, but in the age periods 5-10 to 30-40 inclusive, the female rates were the higher, the difference being most marked in the age period 10-15, when the death-rate of females was 6·71 higher than that of males. Throughout life the mean death-rate among males was 43.42 per 1,000 against 44·43 among females.

Lower Burma.—The number of births in Lower Burma in 1903 was 184,561, the highest number yet recorded. The birth-rate was 33·54 per 1,000 against 31·57 in the preceding year. The highest district birth-rate was 46·01 per 1,000, recorded in Thayetmyo, followed by 43·64 and 42·76 in Tharrawaddy and Henzada, respectively; and the lowest rates were 26·63 in Toungoo, 25·61 in Thaton and 17·95 in the urban district of Rangoon, where it is reported the closer supervision now being exercised by the health officer and his assistant is bringing about an improvement in registration. In rural areas the mean birth-rate was 34·52 as compared with 26·50 in the towns. In four towns the recorded birth-rate exceeded 40 per 1,000, namely, the little town of Zigon, where a birth-rate of 89·73 in 1902 was succeeded by a rate of 82.49 in 1903, Gyobingauk 42·79, Allanmyo 41·54, and Kawkareik 41·34. The percentage of male to female births averaged 108, ranging from 119 in Mergui to 101 in Henzada.

The number of deaths recorded was 132,767 or 15,381 more than in 1902, and the death-rate rose from 21·16 in that year to 24·13. Considerably the highest district death-rate was 34·57 recorded in the Rangoon town district, followed by rates of 30·83 and 30·45 in Thayetmyo and Pegu, respectively; the lowest district rates were 17·41 recorded in Tavoy, 16·44 in Thaton and 15·58 in Mergui. In rural areas the mean death-rate was 22·98 against 32·33 in the towns, in which the rates ranged from 66·57 in Zigon and 46·05 in Kyaiklat to 21·32 in Letpadan and 15·18 in Mergui.

Buddhists died at the rate of 24·64, Hindus at the rate of 23·44, Muhammadans and "other classes" at the rates of 20·63 and 20·57, respectively, and Christians at the rate of 16·80.

Male infants died at the rate 220·52, and female infants at the rate of 168·12 per 1,000 born; boys and girls over one year and under five years of age died at the rates of 29·16 and 25·37 per 1,000 living at those ages at the time the census was taken. At all age periods, except 30-40, the male death-rates were the higher, the mean death-rate among males being 25·55 and among females 22·52.

Upper Burma.—In twelve towns of Upper Burma with an aggregate population of 294,715, made up of 149,314 males and 145,401 females, both births and deaths are registered; in the province generally only deaths are registered. The mean birth-rate of the towns was 37·48, the rates in individual towns ranging from 55·17 in Kyaukse to 30·62 in Minbu. The mean recorded percentage of male to female births was 105, the percentages in the different towns showing extraordinary variation, the extremes of which were 123 in Salin and 73 in Kyaukse.

In Upper Burma the number of deaths recorded was 62,941, and the recorded death-rate was 21·80, ranging in the districts from 38·19 in Kyaukse to 12·02 in Meiktila. In rural areas the mean death-rate was 19·83 against 39·20 in the towns, in which the rates ranged from 64·58 in Kyaukse to 25·46 in Yamethin.

Christians died at the rate of 17·58, Muhammadans at the rate of 20·54, Buddhists at the rate of 21·81, and Hindus and "other classes" at the rates of 23·21 and 31·95, respectively. At all age periods, save 20-30 and 30-40, the male death-rates were the higher, the means being 22·59 per 1,000 among males, and 21·10 per 1,000 among females.

Ajmer-Merwara.—The number of births recorded in this small province during 1903 was 14,061, equal to a ratio of 29·48 per 1,000 of population, against a quinquennial mean of 27·67. The quinquennium includes the years 1900 and 1901, when the number of births fell below 8,000, and the year 1902 when the number rose to 17,207. The number of males born to every hundred females born was 117·66, while in 1902 and 1901 the percentages were 115·25 and 119·15, respectively.

The number of deaths registered in 1903 was 13,720, equal to a death-rate of 28·77 per 1,000. The mortality was lower than in either 1902 or 1901, when the deaths recorded numbered 15,672 and 15,798, yielding death-rates of 32·86 and 33·13, respectively. The quinquennial mean was 53·06, but includes the year 1900, when the death-rate recorded was 119·97 per 1,000. The death-rate in the districts was 24·20, and in the towns 41·01; the corresponding rates in 1902 were 29·88 and 40·85.

Hindus died at the rate of 29·66, and Muhammadans at the rate of 32·40 per 1,000, as compared with rates of 35·05 and 31·49, respectively, in the preceding year.

The recorded death-rates among male and female infants were almost identical, being 260·7 for males and 260·5 for females per 1,000 of registered births, which represents an increase on the rates of 219·15 for males and 214·41 for females in 1902.

As was the case in the preceding year, the male death-rates were the higher at all age periods, except 15-20, 20-30 and 30-40. The average death-rates of the sexes were 28·52 among males and 29·05 among females.

History of the Chief Diseases.

Mortality from different diseases.—The following table shows at a glance the number of deaths and the death-rates per 1,000 of population recorded in India from each of the chief diseases during 1903 and 1902. It will be seen that the mortality from many of the other diseases was, as usual, quite insignificant as compared with that recorded under the heading "fevers," and that in 1903, with the exception of small-pox, there was an increase under all headings.

Disease.	Number of deaths.	Number of deaths.	Death-rate per 1,000.	Death-rate per 1,000.
	1903.	1902.	1903.	1902.
Cholera	312,854	224,136	1·37	1·01
Small-pox	93,693	115,443	·41	·52
Plague	865,578	583,937	—	—
Fevers	4,459,237	4,279,551	19·66	19·17
Dysentery and diarrhœa	273,459	235,750	1·21	1·06

Cholera in India in 1903.—The number of deaths from cholera recorded in British territory during 1903 was 312,854, equal to a death-rate of 1·37 per 1,000 of the total population under registration. If the deaths recorded in the native States from which returns were received be added, the total amounts to 314,298. In the previous year 224,136 deaths from cholera were recorded in British territory, giving a ratio of 1·01 per 1,000 of population. The increase in mortality from this disease was shared by all the British provinces, except Assam, Madras, Bombay and Ajmer-Merwara. So far as can be gathered from a study of the reports of provincial Sanitary Commissioners, it appears that the increased prevalence of the disease is to be attributed partly, at any rate, to the fact that 1903 was the year when the great Kumbh Mela, which takes place once in twelve years, was held. The chief bathing day, which fell on the 13th of April, was attended by about 400,000 people, and all went well until the 16th, when some three-fourths of the people had dispersed and the general and sanitary arrangements were being broken up. It is said that on this day cholera broke out with great virulence among a sect of faquirs, and that from them it rapidly spread to other pilgrims still remaining in and about Hardwar, and it is reported that as these people dispersed to their homes, they carried the disease with them into other parts of the United Provinces, into the Punjab, the North-West Frontier Province and the Central Provinces. As regards the seasonal prevalence of cholera during 1903, the disease remained more or less in abeyance over the greater part of the country during the first three months of the year, and even until the end of April the total number of deaths was considerably less than had been recorded during the same period in 1902. From the beginning of May the prevalence of the disease increased rapidly to a maximum in July, and decreased equally rapidly during August, September and October, which was the month of least prevalence. In November and December a second but smaller rise in the mortality from cholera occurred. The greatest numbers of deaths from the disease were recorded during the year in Bengal, the United Provinces, the Madras Presidency and the Punjab; and the highest death-rates in Bengal, Assam, Upper Burma, the United Provinces, Lower Burma and the Punjab.

Deaths from Cholera in British Provinces, by months, during the year 1903.

* Excluding Upper Burma—figures received late.

Cholera in Bengal.—In Bengal in 1903 the total number of deaths recorded as due to cholera was 203,405, or 2·73 per 1,000 of the population, as compared with 150,971 or 2·02 per 1,000 in 1902, and 110,753 or 1·48 per 1,000 in 1901. The mortality during 1903 was higher than in any of the previous six years, except 1900. No district was entirely free from the disease which attacked 27,309 villages against 22,642 in 1902, and assumed an epidemic form in 116 registering circles against 67 in that year. The district of Champaran in the Patna division suffered most severely and

lost 7·69 per 1,000 of its population from this cause. Other districts in which the mortality from cholera was very high were Puri in the Orissa division (6·31 per 1,000), Shahabad in the Patna division (6·12 per 1,000), 24-Parganas in the Presidency division (5·82 per 1,000), and Cuttack in the Orissa division (5·13 per 1,000). In Champaran the disease prevailed most severely in July and August, causing during this period 9,500 deaths in the district. In Shahabad the disease caused more than 10,600 deaths during the period from June to August. The Civil Surgeon of this district was of opinion that the epidemic was aided by the late commencement of the monsoon, the disease greatly diminishing when rain fell in sufficient quantity to flush and cleanse the sources of drinking-water supply. This was the experience of Civil Surgeons in other districts. In twenty-five districts during the cholera outbreaks tanks and wells were disinfected. In most cases a systematic record of results was not maintained, but the measure is generally said to be attended with beneficial results. In Puri, however, in spite of the wells having been disinfected before the commencement of the cholera season, the second highest death-rate from cholera among all the districts was recorded.

The highest death-rates from this disease recorded in towns were 18·71 per 1,000 in Motihari in the Champaran district, 14·07 in Faridpur, and 12·13 in Nadia, both in the Nadia district, and 11·74 in Raghunathpur in the Manbhum district. Among rural areas the highest death-rate (17·41 per 1,000) was recorded in Basudebpur in the Balasore district.

Among the European seamen of the port of Calcutta there were only 4 deaths from cholera, and there were 69 among the native floating population.

Cholera in Assam.—The number of deaths attributed to cholera in Assam during 1903 was 8,360, equal to a ratio of 1·58 per 1,000 of the census population. In the previous year the number of deaths from cholera recorded in this province was 12,658, giving a ratio of 2·40 per 1,000 of population. With the exception of Bengal the death-rate from cholera in Assam during 1903 was the highest among the provinces for the year, and the diminished mortality as compared with that of 1902 was confined almost exclusively to the districts of Cachar and Sylhet in the Surma Valley. Both these districts had suffered severely in 1902. In all the districts of the Brahmaputra Valley, except Kamrup and Lakhimpur, the death-rates from cholera were higher than in the previous year, and in the Darrang and Nowgong districts, both of which had been comparatively free from cholera during 1901 and 1902, the death-rates reached the high totals of 3·76 and 6·73 per 1,000 of population, respectively.

The death-rate from cholera among tea-garden coolies was less than that among the general population of Assam, but in certain districts, such as Kamrup, Sibsagar and Lakhimpur, where the general population suffered only slightly, the tea-garden coolies suffered severely. On the other hand, the tea-garden coolies in the Nowgong and Darrang districts, where the general population suffered so severely, enjoyed comparative immunity from the disease.

The death-rate from cholera among tea-garden cooly immigrants rose from ·9 per 1,000 in 1902 to 1·6 per 1,000 in 1903, but the ratio is a low one compared with that of most previous years of record.

Cholera in the United Provinces.—The total number of deaths from cholera recorded in the United Provinces during 1903 was 47,159, equal to a ratio of ·99 per 1,000 of population, as compared with a total of 25,160 and a ratio of ·53 during 1902. It is possible that in the ordinary course of events there would have been but little cholera in the United Provinces during 1903, for the total number of deaths recorded from this disease up to the end of March was less than half the number recorded during the same period in 1902. But in April the Kumbh Mela, which takes place once in twelve years, was held at Hardwar. Pilgrims began to arrive in the middle of March, and it is estimated that by the end of the month some 100,000 people were present. Many remained until the Dikhauti fair on April 13th, and it is estimated that between the 28th March and this date an average of 200,000 to 250,000 pilgrims were constantly present on the fair site and in the neighbouring towns of Kankhal and Jwalapur. During this period, however, only 11 cases of cholera are reported to have occurred. The great bathing day on the 13th April was attended by about 400,000 people. By the 16th April about three-fourths of these people had dispersed, and the general and sanitary arrangements were being broken up. It is reported that on this day cholera commenced with great virulence

among the Bairagis, a sect of faquirs, and that from them it spread to other pilgrims still remaining in and about Hardwar, who as they dispersed to their homes, are said to have carried it with them to other parts of the United Provinces. Over one-third of the total number of deaths from cholera in the United Provinces during 1903 occurred in July. During this month the temperature was considerably in excess of the normal, and the rainfall very scanty. In August, coincidently with a slight to considerable excess in the rainfall over the different divisions, the cholera mortality began to decline rapidly.

The highest district death-rates were recorded in Garhwal, Ballia, Dehra, Dun, Almora, Ghazipur and Rae Bareli, and the highest town mortalities were those of Bansdih (11·87 per 1,000), Ballia (8·38 per 1,000) and three other towns with ratios ranging from 8·32 to 7·00 per 1,000. In only 38 towns, as compared with 57 in 1902, no death from cholera was recorded.

In Ballia, the Dadri fair, at which it was estimated about 500,000 people were present, took place in November, but no case of cholera was reported to have occurred.

Cholera in the Punjab.—The Punjab had been almost free from cholera in 1901 and 1902, only 180 deaths from it being recorded in the former year and only 371 in the latter; but in 1903 cholera was present in epidemic form, and 14,688 deaths from this disease, equal to a ratio of ·73 per 1,000 of the population, were recorded. During the first three months of the year no death from cholera was reported in any part of the province, and it was not until after the Hardwar fair in the United Provinces in April that the epidemic in the Punjab began. It has already been mentioned that cholera broke out at this fair about the 16th of April, and it is said that immediately after the fair cases began to occur in different parts of the Punjab among pilgrims returning from Hardwar. There were 229 deaths registered from cholera in April in 15 districts, and in each district the first case was said to have been a pilgrim returning home from the Hardwar fair. During May 959 deaths from cholera were recorded, during June 3,054, and during July 6,184. In August the epidemic began to decline considerably, 2,300 deaths being recorded during that month, 1,512 during September, and 431 during October. The highest death-rates from the disease were recorded in the districts of Ludhiana (3·06 per 1,000), Ferozepore (3·01), Lahore (2·32) and Umballa (2·11). The highest death-rates recorded in towns were 16·51 per 1,000 in Sadhaura in the Umballa district, 12·22 in Sangla in the Gujranwala district, 8·17 in Kasur in the Lahore district, and 7·87 in Palwal in the Gurgaon district. In four other towns ratios of over 5 per 1,000 were recorded.

Cholera in the North-West Frontier Province.—In 1903 in the North-West Frontier Province 1,354 deaths from cholera, equal to a ratio of ·68 per 1,000 of the population, were recorded. In the previous year no death from cholera had been returned, and the epidemic which prevailed during the year under review is said to have been traceable to the importation of cases from Hardwar in the United Provinces, either directly or viâ Rawalpindi. The first death from cholera reported in the North-West Frontier Province is said to have occurred in Peshawar on the 21st of April. By the 24th of April, 59 villages in the Peshawar district were affected. Early in May the disease invaded the Kohat district, in June it spread to Bannu and at the end of that month the Hazara district was also affected. The district of Dera Ismail Khan was free from the disease. In the Kohat district 2·16 per 1,000 of the population were reported to have died from cholera, in the Bannu district ·71, in the Peshawar district ·60, and in the Hazara district ·54.

Cholera in the Central Provinces and Berar.—In the Central Provinces and Berar the total number of deaths recorded as due to cholera in 1903 was 437, or ·03 per 1,000 of the population, as compared with a total of 44 and a ratio of ·003 in 1902. Of the total number of deaths 363 were recorded in the Central Provinces and 74 in Berar. A small outbreak causing 31 deaths in three months commenced in the Bilaspur district of the Central Provinces in April, and a more important one prevailed in the Murwara district of the Vindhyan division during June and July. In this outbreak the disease was said to have been probably introduced from the United Provinces by lime-quarry workers.

The only outbreak in Berar commenced in the Wun district in August. It caused three deaths in that month, 21 in September, 49 in October, and one in

November. An outbreak which caused 115 deaths in the Chanda district of the Central Provinces was said to have originated from this epidemic in the Wun district of Berar.

Cholera in the Madras Presidency.—In the Madras Presidency there were 27,393 deaths recorded as due to cholera in 1903, giving a ratio of ·7 per 1,000 of population, as compared with a total of 29,769 and a ratio of ·8 per 1,000 in 1902. The districts of Anantapur, Kurnool, and the Nilgiris were the only ones in which no death from cholera was recorded. The highest death-rates in districts were 2·2 per 1,000 of population in Malabar, 2·1 in Trichinopoly, 1·8 in Salem, 1·7 in Tanjore and 1·6 in Madura. In Malabar 6,157 deaths from cholera were recorded and in Madura 4,422. The highest death-rates recorded in towns were 10·4 per 1,000 in Devakkottai and 9·8 in Ramnad, both in the Madura district, 9·8 in Salem in the Salem district, and 9·6 in Ponnani in the Malabar district. The death-rate recorded in the town circles of the Presidency was ·9 per 1,000, and in the rural districts ·7 per 1,000.

Cholera in Coorg.—No death from cholera was recorded in this small province during 1903. There had been no cholera in Coorg during 1902, but in 1901 the disease caused 58 deaths.

Cholera in the Bombay Presidency.—As in 1902 there was again comparatively little cholera in the Bombay Presidency during 1903. Only 1,825 deaths from this disease were recorded during 1903 as compared with 3,230 in 1902, the death-rates per 1,000 of population being respectively ·09 and ·17. Although a few deaths from cholera were recorded in nine other districts, the disease prevailed in epidemic form in only four districts of the Sind Province, in which districts 1,752 deaths from cholera occurred. During the first four months of the year the disease was absent from the whole Presidency, excepting Bombay city (5 deaths) and the town of Broach (1 death). In May, however, an epidemic commenced in the Sukkur, Larkhana and Upper Sind Frontier districts of Sind. The first case in this outbreak was reported from Thul (old) in the Jacobabad district as having been imported from Hardwar, and another case, imported from the same place, was reported in Shikarpur town on the 3rd of May. Indigenous cases and deaths then began to occur in this town. Sukkur was next attacked and then Rohri; afterwards the disease gradually spread into the rural circles of the Sukkur, Larkhana and other districts. Fortunately, the disease remained very localised, and throughout the whole Presidency only 160 villages were attacked during the year. Of these no less than 152 or 95 per cent. were in Sind. There was no cholera in any of the seven cantonments in the Presidency.

Cholera in Burma.—In Lower Burma during 1903 there were recorded as due to cholera 5,346 deaths, equal to a ratio of ·97 per 1,000 of population, as compared with 1,844 or ·33 per 1,000 from the same cause in 1902. The greatest numbers of deaths were recorded during April and May, and the fewest during September, December and October. The highest death-rates recorded in districts were 3.07 per 1,000 in Akyab, 1·80 in Amherst and 1·44 in Thongwa; in towns the highest death-rates were 10·78 in Nyaunglebin, 10·12 in Maubin and 7·97 in Kyaiklat. The total number of persons reported to have been attacked with cholera was 8,532, with a case mortality of 63 per cent.

In Upper Burma the total number of deaths recorded as due to cholera during 1903 was 2,887, as compared with only 57 during 1902. The disease prevailed in every district, but the Pakokku and Minbu districts suffered most severely. The death-rates from the disease in these districts were 2·36 and 2·05 per 1,000, respectively. The highest death-rates recorded in towns were 7·09 per 1,000 in Minbu, 6·94 in Myingyan, and 6·23 in Shwebo.

Cholera in Ajmer-Merwara.—No death from cholera was recorded in this province during 1903. The numbers of deaths reported under this heading in 1902 and 1901, respectively, were 32 and 50.

Anti-cholera inoculation.—The total number of inoculations performed at the Purulia depôt in Bengal during the year was 1,904, as compared with 3,144 in 1902 and 3,453 in 1901. In addition 298 operations were performed during the month of

December at the recently opened inoculation depôt at Asansol. The subjects were all cooly emigrants proceeding to the tea districts of Assam. Out of 2,633 uninoculated coolies proceeding by the steamers, plying between Goalundo and Dibrugarh, 68 or 2·58 per cent. were said to have been attacked with cholera, 16 of the cases proving fatal; while out of the 199 inoculated coolies who were on board these steamers 4 or 2·01 per cent. were reported to have been attacked by the disease, one of the cases ending fatally.

SMALL-POX.

The death-ratio per 1,000 of population from small-pox fell from ·52 in 1902 to 41 in 1903. The total number of deaths recorded during 1903 was 93,693, as compared with 115,443 in 1902 and 89,378 in 1901.

Table showing the Deaths from Small-pox registered in British Provinces, by months, during the year 1903.

PROVINCES.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL. 1903.	RATIO OF DEATHS PER 1,000 OF POPULATION 1903.

In Bengal the number of deaths from small-pox, which had been steadily increasing year by year since 1899, fell during 1903 to 30,459, as compared with 57,430 in 1902. In Assam the death-rate from small-pox during 1903 was ·21 per 1,000 of population as compared with 1·26 per 1,000 in 1902, but the diminished prevalence of the disease was chiefly confined to the Surma Valley districts, which had suffered so severely from small-pox in the previous year. The mortality in the districts of Darrang, Nowgong, and Sibsagar in the Brahmaputra Valley was higher than in 1902, but in no district was there a marked epidemic. The practice of inoculation is still carried on in some districts, and it is said that many of the inhabitants of the Nowgong district not only disbelieve in the protective efficacy of vaccination, but suspect it of producing small-pox. In the United Provinces 21,950 deaths from small-pox were recorded during 1903 as compared with 4,976 in 1902. The ratio (·46 per 1,000 of population) is the third highest among the provinces for the year. The highest death-rate recorded in districts was 3·46 per 1,000 in Rae Bareli, and the highest in towns 6·22 in Mau (Azamgarh). In the Punjab 15,635 deaths from small-pox, equal to a ratio of ·78 per 1,000 of population, were recorded during 1903 as compared with a total of 11,629 and a ratio of ·58 in 1902. The district of Rawalpindi, in which 2,614 deaths were recorded, was most severely affected, and the best-vaccinated district (Kangra) had, as usual, the lowest death-rate. The death-rate in municipal towns was higher than in rural circles. In the North-West Frontier Province the death-rate from small-pox in 1903 was 1·35 per 1,000 of population as compared with ·54 in 1902. The total number of deaths recorded from the disease was 2,694, and of this number no less than 2,500 were children under 10 years of age. The Vaccination Act is in force in only two towns, in both of which the ratio of mortality from small-pox was low. In both the Central

Provinces and Berar the recorded mortality from small-pox was considerably less during 1903 than in the previous year, but the provincial Sanitary Commissioner says that the district reports show that a number of deaths which were attributed to measles and chicken-pox were probably due to small-pox. In Berar only 104 deaths from small-pox were recorded, but no less than 571 from measles and chicken-pox. In the Madras Presidency 15,015 deaths from small-pox were recorded during 1903, a considerable decrease as compared with the previous year. A scheme for the reorganisation of the vaccination department and for compulsory vaccination in rural tracts has been submitted to the local Government. In the Bombay Presidency the number of deaths recorded as due to small-pox during 1903 was slightly greater than during 1902. Of the total of 2,732 recorded deaths 1,460 occurred in the city of Bombay. In Lower Burma the recorded number of deaths from small-pox fell from 1,565 in 1902 to 1,266 in 1903, but in Upper Burma the mortality from this disease increased.

Plague.

Since the commencement of the present epidemic of plague in India, in 1896, the disease has been steadily gaining ground year by year. In 1898, the first year in which the mortality from plague was shown in a separate table in this report, 89,265 deaths from the disease were recorded. In the following year the number of recorded deaths reached the total of 102,369. In 1900 the recorded deaths decreased to 73,576, but in 1901 the number, viz., 236,433, far exceeded the combined totals of the two previous years. A further increase to a total of 452,865 deaths was recorded in 1902, but even this figure is small compared to that of 1903, when no less than 684,445 deaths from plague were returned. As compared with other causes of death in 1903 the mortality from plague was more than twice as great as that from cholera, two and a half times as great as that from dysentery and diarrhœa, and more than seven times as great as that from small-pox. The total number of deaths recorded under the heading "plague" was about one-seventh of the total number recorded under the heading "fevers." As in the three preceding years the month of highest mortality during 1903 was March. The year 1903 is the third since 1898 in which the month of minimum mortality from the disease has been July; in each of the other years, except 1900 and 1902, it was June. As would be expected, however, the months of maximum and minimum prevalence of plague vary in different parts of India. During 1903 all the provinces of India were more or less affected except Burma, where only 9 deaths from plague (all being imported cases) were recorded, and Baluchistan, where only 3 deaths were recorded.

In this place it is usual to give a statement of the more recent researches upon plague. To a great extent such a statement is but a record of contradictory results obtained by different observers, and from time to time it is necessary to attempt to select the wheat from the chaff and to summarize such facts as appear to be undisputed, lest, amidst a mass of conflicting evidence, we forget the fundamental principles upon which sound prophylaxis can be based.

The bacillus.—In the first place all observers are agreed that plague is caused by the *b. pestis*, and that it is a disease which simultaneously attacks men and certain of the lower animals, especially the rat. Until lately no varieties of the true *b. pestis* were admitted, but Klein has recently suggested the possibility of there being at least two types of the bacillus, viz., (1) a virulent type bred in the human subject, which on gelatine exhibits raised colonies with filmy irregular margins, the bacilli being cylindrical in shape when taken from recent cultures, and (2) a less virulent type bred in the rat, exhibiting rounded translucent colonies on gelatine with coccus-like forms on culture. The rat is susceptible to both these varieties, but it is possible that only such human beings as are highly susceptible can be infected with the less virulent type. Dr. William Hunter, the Government bacteriologist of Hong Kong, is evidently of the same opinion as Dr. Klein upon this matter. He considers that rats suffer from two forms of plague an acute and a chronic; the acute form is produced by the ordinary virulent bacillus met with in man, and the chronic by a strain of the same bacillus which, by continued passage through rats, has become avirulent. The existence of these two varieties of the plague bacillus is important, for it enables us to explain certain questions in the epidemiology of plague which before were not clear.

Length of life of the bacillus in nature.—In the second place it is essential to come to a definite conclusion regarding the limits of life of the bacillus outside the bodies of human beings or of animals. Upon this point there is considerable difference of opinion. Observers have kept pure cultures of the bacillus alive for months or even years by protecting them from light, from drying and from heat, but such experiments afford no index of the length of life of the bacillus under the conditions it meets with in nature. Under such conditions the presence of saprophytic organisms, the action of heat, of drying, &c., are known to be very harmful to it, and no one has so far succeeded in finding plague bacilli in the air, in dust, or even in the earth unless it has been very recently contaminated with sputum or other material infected with the bacilli. The latest experiments upon the vitality of the bacillus in soil and in buildings are those made by Mr. Watkins-Pitchford, F.R.C.V.S., the Government bacteriologist of Natal. He found that in soil, the bacillus died out in five weeks and in buildings containing stores of grain and other produce in from four to eight weeks. If we may assume that the life of the bacillus as a saprophyte is thus limited, it would appear that for the maintenance of the disease between epidemic outbreaks infected human beings and animals are the chief factors at work.

Mode of spread of the disease.—This brings us naturally to the mode of spread of the disease. Even during the oldest recorded epidemics of plague a connexion between human plague and rat plague was recognised, but the nature of the connexion is a matter upon which opinions are still divided. Statements are made that epidemic human plague may exist in the absence of rat plague, that human plague may exist for some time previous to the appearance of the disease among rats, and that rat plague does not in every case lead up to an epidemic among men. It was with the intention of attempting to arrive at a solution of the problem regarding the exact connexion between human plague and rat plague that Dr. W. Hunter commenced in 1902 a systematic research into epidemic and epizootic plague in Hong Kong. During that year 117,839 rats were bacteriologically examined and during 1903, 101,056 rats. In 1902, 2,015 of the rats examined were found to be plague-infected, and in 1903 the number infected was 3,744. Charts were prepared showing side by side the number of cases of plague occurring each week among human beings and the number of plague-infected rats found. Separate charts were made for each district and another for the whole of Hong Kong. Considering these charts for the two years the following conclusions seem justifiable: (1) the curves of rat plague and of human plague are remarkably similar; (2) at a definite period each year the rat plague curve rises rapidly and is followed at an interval of about a fortnight by a similar rise in the human plague curve; (3) the point of maximum intensity of human plague is about a fortnight later than that of rat plague; (4) the rat plague curve declines and is followed by a similar fall in the human plague curve; (5) the human epidemic becomes extinct, but the rat epidemic does not; it remains in abeyance for a week or two and then recrudesces and remains at a low but more or less constant level until the following year, when its curve again suddenly shoots upwards to be followed within a very short time by the yearly epidemic in men; (6) rat plague is, therefore, epizootic continuously but human plague is only epidemic during the acute exacerbations of the epizootic.

If Dr. Hunter is correct, it appears to follow that epidemics of human plague in Hong Kong are directly dependant upon previous epizootics among rats. The fifth and sixth conclusions are very important for they serve to explain the bridging over of epidemics from one year to another. It has already been mentioned that rats suffer from two forms of plague, an acute and a chronic, and that the latter is caused by an avirulent type of the bacillus. Dr. Hunter has found that it is the chronic form of the disease which is present in rats during the intervals between human epidemics, the latter being present only during the prevalence of acute rat plague caused by the ordinary virulent variety of the bacillus. He considers that the yearly recrudescence of acute rat plague is occasioned by the infection of fresh generations of rats which are highly susceptible to plague infection, and that the recrudescence of acute rat plague, and, therefore, of the human epidemic, occurs at the period of the year when rats are most prolific.

In connexion with the spread of plague by other animals than rodents it will be remembered that in 1902 Professor Simpson stated, as a result of his investigations in Hong Kong, that "the experiments undertaken demonstrate that pigs,

calves, buffaloes, sheep, hens, ducks, geese, turkeys, and pigeons are, in addition to rats, susceptible to plague, and particularly so when fed with plague material." The great importance attaching to this announcement has led several observers to repeat Professor Simpson's experiments, and the result has been to show either that Professor Simpson was mistaken in the diagnosis of the disease from which the animals used in his experiments died, or that the susceptibility of animals in Hong Kong to plague is very different from that of animals in other countries. A careful research in connexion with this subject has lately been carried out by Major Bannerman, I.M.S., at the Plague Research Laboratory in Bombay, and another by Mr. Watkins-Pitchford, F.R.C.V.S., in Natal. In the Bombay experiments 4 pigs, 4 turkeys, 2 calves, 4 geese, 4 fowls, and 4 ducks were used and the methods prescribed by Professor Simpson were followed as exactly as possible. The experiments were carried out by "cutaneous inoculation," by feeding, and by subcutaneous injection, and in every case the results were entirely negative, thus confirming the experiments previously carried out in Bombay by the German Plague Commission. Mr. Watkins-Pitchford reports that in Natal repeated endeavours were made to induce a fatal form of plague by the ingestion of infected materials and by the inoculation of virulent cultures and blood, as well as by close contact with an animal in a highly infectious condition. None of the 20 hens, 10 pigs, and 2 calves used in these experiments contracted plague. It appears then that domestic animals in India and Natal are not liable to contract plague by ingestion, scarification, or subcutaneous injection.

Mode of Infection.—Assuming that Dr. Hunter's conclusions regarding the connexion between rat plague and human plague are correct, it becomes necessary to attempt to explain how rat plague is usually communicated to man. The avenues of infection in plague considered to be important are, the skin, the alimentary tract and the respiratory tract. Regarding the respiratory tract but little need be said, for most, if not all, observers are agreed that it is chiefly of importance in connexion with cases of primary pneumonic plague which are caused by the direct conveyance of bacilli from one person to another by means of microscopic particles of sputum scattered about during the acts of coughing, sneezing, or even speaking. As regards the skin, Albrecht and Ghon made the important observation, which has been amply confirmed, that plague bacilli, when rubbed into the shaved skin of a rat or guinea pig, always occasion a lethal infection. It is probable that a slight abrasion of the skin is a favouring circumstance in this mode of producing the disease, and in performing "cutaneous inoculation" with animals Klein makes a practice of scraping off the superficial epidermis and of slightly scarifying the exposed surface before rubbing in the contaminated material. He is evidently of opinion that the skin is the usual avenue of infection in plague. Hunter, on the other hand, while not denying that cases are frequently met with in which plague infection has occurred through an abrasion of the skin, says that the evidence at his disposal is decidedly against the conclusion that the skin is the common portal through which the plague bacillus gains an entrance into the bodies of men or animals. Influenced, doubtless, by the results reported by Professor Simpson referred to above, he considers the alimentary canal to be perhaps the most important point of entry of the bacillus into the body. Some of the grounds upon which he founds this conclusion are the following: (1) The symptoms complained of by plague patients in the earliest stages of the disease are often referable to the gastro-intestinal tract; (2) the condition found in the gastro-intestinal tract on post mortem examination is strongly suggestive of alimentary incorporation of the bacillus; (3) the bacillus is present very abundantly in the fæces of men and animals suffering from plague; (4) the bacillus is little if at all affected by the gastric juice; (5) experimental evidence in animals yields constant positive results. Pigs, fowls, sheep, monkeys, &c., if fed on plague-infected material, contract the disease with certainty; (6) in the rate the usual mode of infection is by the mouth; (7) food and articles of diet have been found infected with plague bacilli; (8) vermin such as flies, cockroaches, ants, &c., may harbour plague bacilli and convey the virus to food used by men or animals. Several of these reasons could be used equally well for an argument in favour of infection by the skin, and some of them are directly contradictory to the experience of other workers. The negative results obtained by Albrecht and Ghon in feeding experiments upon pigs and other animals were referred to in last report, we have seen that feeding experiments failed in Bombay and Natal, and Klein has lately published an account of some experiments on rats which point to infection

by the alimentary canal being of very rare occurrence in these animals. He points out that the readiest means of giving plague to a rat is by cutaneous inoculation or by subcutaneous injection, that amongst half grown and adult sewer rats an animal without any wound or abrasion is rather rare, that plague bacilli are present in the fæces and urine and are therefore distributed over any article with which the dejecta come in contact and that in this way it is easy to understand how the rat (with its frequent cutaneous wounds) becomes infected. He also points out that by whatever way, subcutaneously or cutaneously, a rat is infected, the abdominal viscera always participate in the disease, so that the presence of lesions in the intestines and mesenteric glands cannot be regarded as having been due exclusively to infection by food. In addition, out of 20 rats fed with the viscera of guinea pigs and rats dead of typical plague, only one died of plague, and even in this instance it was not improbable that the lungs had been the site of entrance of the virus.

The evidence is so conflicting that it is impossible at present to arrive at a definite conclusion as to the usual avenue of infection in plague, and it may well be that this will vary with the circumstances. In connexion with infection by way of the skin, it is, perhaps, no over-statement of the trend of present opinion to say that infection by the bites of fleas, bugs and other suctorial insects is now regarded by the majority of observers as far less probable than at the time of Simond's original suggestion. The opinions of Galli Valerio, Kolle, Nuttall, and Dieudonné on this subject were referred to in last report. Simpson and Hunter have also endeavoured to procure the infection of healthy rats and monkeys by plague-infected rat fleas with entirely negative results. Klein has also failed to produce infection in healthy rats by this method. In connexion with infection by way of the alimentary canal, Hunter attributes an important *rôle* in the spread of plague to flies and especially to cockroaches. During the epidemic of plague in Hong Kong in 1903 he examined a large number of flies, and on the bodies of at least 75 per cent. of those examined plague bacilli were found. On cockroaches also he found plague bacilli. There seems no reason to doubt that whether we regard the usual avenue of infection in plague to be the alimentary canal or the skin, the danger of the spread of plague bacilli by non-suctorial insects is very great.

Conclusions as regards prophylaxis.—It is not possible, for the reasons given above, to state definitely the exact mode by which rat plague is communicated to human beings, but if we accept the conclusion that the annual recrudescence of human plague epidemics is directly dependent upon a previous epizootic among rats, it is a secondary matter from the point of view of prophylaxis, by what mode the bacillus of rat plague gains entrance into the human body; whatever the exact mode of transference there can be no doubt of the importance of measures directed against rats, for whatever is effected by other measures, the yearly epizootic rat plague will still recur, to be followed inevitably by epidemic human plague. Whether Dr. Hunter's conclusions are correct or not they certainly point the way in which research might profitably be carried out in India. The seasonal prevalence of plague in this country is as definite as in Hong Kong, and it should not be difficult to show whether the bridging over of epidemics is dependent upon chronic infection in rats, whether the commencement of the yearly epidemic occurs at the season when fresh generations of rats appear, as is reported to be the case in Egypt, and whether the human epidemic follows an acute exacerbation of the epizootic among rats. If such should be shown to be the case an energetic campaign against rats carried out during the interval between the human epidemics might possibly meet with success. This is a measure which, it need scarcely be said, has been carefully considered by the authorities, but the very obvious difficulties, arising chiefly from the prejudices and apathy of the people in a matter which demands their willing co-operation, have hitherto been deemed to render the possibility of an effective campaign against these vermin more than doubtful, if not dangerous. In sanitary measures which affect intimately the domestic institutions and religious prejudices of the people of this country the authorities are frequently compelled to defer the scientific ideal to considerations which would not apply elsewhere. The sustained experience which the people have now suffered of the prevalence of the disease has gone far to foster the growth of the necessary confidence in the measures directed by Government for their relief, and their co-operation and sympathy may now perhaps be relied on more confidently, if the areas for an experimental effort, in the first instance, be judiciously selected, and the necessary measures be carefully planned.

† 205,462 in Statement No. VI. of the Provincial Sanitary Report.
‡‡All imported cases.

Plague in Bengal.—The mortality recorded from plague in Bengal during 1903 was nearly twice as great as during the previous year, the total number of deaths recorded as due to this disease being 65,680, or a ratio of ·88 per 1,000 of population, as compared with a total of 32,967 and a ratio of ·44 in 1902. The highest death-rates recorded in districts were 10·61 in Saran, 9·69 in Calcutta, 7·19 in Patna and 3·87 in Shahabad. The disease was present in 29 districts in 1903 as compared with 24 in 1902, and in most districts where the disease occurred during both years the death-rates were higher in the former than in the latter year. The monthly mortality from the disease showed the same peculiarity as regards rise and fall as had been noticed in previous years, viz., a rise to the maximum in March, a steady fall month by month to the minimum in August, and a recrudescence in September and subsequent months to the end of the year.

It appears that throughout the district of Saran the people practised evacuation of villages very largely, but it is said that their general attitude towards the disease was one of marked apathy. Inoculation met with little success in this district, but disinfection was in many cases asked for. In Patna, on the other hand, chemical disinfection was said to be unpopular, though desiccation by burning cowdung cakes on the floors was said to have been understood by all and to have been carried out by many.

Plague in Assam.—Assam, which had remained free from plague until 1903, experienced a small epidemic causing 37 cases with 28 deaths in that year. The first cases were detected about the 16th of May in Dibrugarh. It had been noticed for a few days that rats were dying in great numbers, and as the first and most of the other cases occurred in the foreign grain bazaar, in which neighbourhood the dead rats were also found, the first measures taken were based on the supposition that the outbreak was due to the importation of infected grain or rats. The measures were successful, and the last death occurred on the 3rd of July. The disease did not appear in any other part of Assam during the year.

Plague in the United Provinces.—In the United Provinces there was again a great increase in the mortality from plague, 84,499 deaths being recorded from this cause during 1903 as compared with 43,487 during 1902 and 9,778 during 1901. Deaths from plague were reported from 38 districts in 1903 as compared with 34 districts in 1902. The highest death-rates recorded in districts were 11·10 per 1,000 in Cawnpore, 9·07 per 1,000 in Allahabad, 6·69 in Lucknow, and 6·19 in Ballia; and the highest in towns were 35·33 in Sahatwar in the district of Ballia, 29·91 in Cawnpore and 29·44 in Fyzabad-Ajodhya. As in the previous year most deaths from plague were recorded in March and fewest in July. In the spring of 1903 the control of plague measures was placed under the Inspector-General of Civil Hospitals, assisted by a chief plague officer, as part of the general medical administration of the provinces.

Plague in the Punjab.—The total number of deaths from plague recorded in the British districts of the Punjab in 1903 was 192,068 as compared with 175,645 in 1902. In native states 18,629 deaths from plague were reported. The epidemic prevailed from the commencement of the year in 14 districts, and seven more districts became infected later in the year. The largest numbers of deaths in districts were 44,267 in Gujranwala, 25,355 in Amritsar, 24,664 in Lahore, and 23,826 in Jullundur. The disease attained its maximum intensity in April and was at its minimum in August. By a resolution of the Punjab Government important changes were introduced in the measures for dealing with plague and in the administration and control of plague operations. As regards the measures for dealing with plague, the element of compulsion has been almost entirely eliminated, and while the local Government has recognised and provided for the obligation of rendering assistance to the inhabitants of plague-stricken towns and villages, it has left the choice of adopting or neglecting precautionary measures almost entirely to the people themselves. In villages the only occasion on which compulsion may now be resorted to for the adoption of any precautionary measures is in the case of evacuation, and even here compulsion may be applied only to an inconspicuous minority who refuse to leave their houses in opposition to the wishes of the remainder of their fellow villagers. In towns compulsory action is limited to the isolation of houseless or unattended persons suffering from plague. Chemical disinfection by official agency is still advocated both in towns and villages, but in villages it is limited to the initial stage of a fresh outbreak of plague, and in towns, although it is directed that the free disinfection of infected houses and rooms should be offered throughout the epidemic, it is directed to be carried out only if the owners consent to have their clothing and other belongings disinfected. In cases where chemical disinfection is not carried out, the desiccation of infected houses and rooms has been advocated. Inoculation is still freely offered to the people, and all dispensaries in the province in charge of Assistant Surgeons have been provided with inoculation equipment.

Plague in the North-West Frontier Province.—In the North-West Frontier Province during 1903 the number of deaths recorded as due to plague was 49, as

compared with four in 1902. All the deaths occurred in the Hazara district. The earlier cases were probably imported from Dhariwal near Gujranwala, Wazirabad, and Rawalpindi. There was no plague west of the Indus.

Plague in the Central Provinces.—The epidemic of plague which had commenced in the Central Provinces at the end of 1902 extended rapidly and spread widely. During 1903 no fewer than 35,335 deaths from this disease were recorded in the Central Provinces, and even this number is not considered by the provincial Sanitary Commissioner to nearly represent the true plague mortality. He was of opinion that many deaths recorded under the headings of "fevers" and "other causes" were really due to plague, and considered that the actual plague mortality probably exceeded the recorded mortality by about ten per cent. The highest death-rates recorded in districts were 21·95 per 1,000 in Burhanpur, 20·34 in Nagpur, 13·30 in Jubbulpore and 12·75 in Hoshangabad. In the town of Kamptee in the Nagpur district the very high death-rate from plague of 108·11 per 1,000 was recorded, and in the town of Nagpur the high rate of 75·17. Death-rates of between 50 and 60 per 1,000 of population were recorded in the towns of Hoshangabad and Harda in the Hoshangabad district, Barhanpur in the Barhanpur district and Jubbulpore. There were two distinct periods of plague prevalence—the first continued from the previous year and terminated early in May; the second commenced in August and lasted till the end of the year. The highest mortality during the first epidemic occurred in March, and during the second epidemic in November. The attitude of the people in general is said to have undergone a change for the better; they have begun to realize that unless they protect themselves the State can do but little for them. They understand the value of evacuation and the desirability of temporarily excluding arrivals from infected areas. Both inoculation and chemical disinfection are said to be unpopular.

Plague in Berar.—Plague made its first appearance in Berar in 1902, during which year 4,188 deaths from it were recorded. In 1903 the number of deaths reported as having been due to plague in Berar was 16,179. All the districts were more or less affected, and out of a total of 43 towns only eight escaped. A death-rate from plague of 93·12 per 1,000 was recorded in the town of Amraoti and rates of 60 per 1,000 or over were returned in five other towns.

Plague in Madras Presidency.—The total number of deaths from plague recorded in the Madras Presidency during 1903 was 13,006, as compared with totals of 11,362 in 1902 and 3,035 in 1901. As in the previous year the disease was most prevalent during 1903 in the Bellary district, in which it was responsible for a total of 5,896 deaths and a death-rate of 6·2 per 1,000 of population. The Nilgiris came next with a death-rate of 5·6 per 1,000. Out of the total of 22 districts in the Madras Presidency, the disease was during 1903 indigenous in eight and four were entirely free. The highest death-rates from plague recorded in towns were 113·7 per 1,000 in Vaniyambadi, 33 in Tirruppattur, both in the Salem district, 26·5 in Hospet, 20·6 in Rayadrug, both in the Bellary district, and 14·2 in Coonoor and 13·2 in Ootacamund, both in the Nilgiris.

Plague in the Bombay Presidency.—In the Bombay Presidency during 1903 the total number of deaths recorded as due to plague was 281,269, an excess of nearly 100,000 over the figures of 1902, and considerably the largest number recorded in any province during the year. In 1903 the Bombay Presidency has gained the unenviable distinction of being the first, and so far, the only, province in which the recorded mortality from plague has exceeded that from "fevers." The mortality recorded from plague in this Presidency during 1903 was the highest since the commencement of the epidemic in 1896, and all districts were affected except Thar and Parkar and the Upper Sind Frontier.

Plague in the City and Port of Bombay.—In the City of Bombay 20,751 deaths from plague were recorded during 1903, as compared with 18,694 during 1902. The disease prevailed in epidemic form from January to May inclusive. At the inspections of outgoing and incoming vessels and of vessels lying in the harbour, 97 cases of plague were detected. Among the passengers and crew who were sent to the port observation camp from the outward inspections, 39 developed plague and were sent to the Modikhana hospital for treatment.

Plague in Burma.—Only ten cases of plague—all imported—occurred in Burma during 1903. Five of the cases were detected in the port of Rangoon at the medical inspections imposed on all incoming vessels arriving from India or other infected ports. Two cases occurred at Moulmein on a steamer from Bombay and two on a steamer from Calcutta. The remaining case was that of a military policeman who arrived in Rangoon town from Satara in the Bombay Presidency. The successful resistance to the invasion of plague from infected centres justifies the stringency with which the rules in force in Burma have been carried out.

Plague in Baluchistan.—In Baluchistan three deaths from plague were reported during 1903 as compared with 30 during 1902. There were in all only four cases reported during the year. All were imported cases and the disease did not spread.

Plague in Rajputana and Ajmer-Merwara.—In Rajputana 2,442 deaths from plague were recorded during 1903 as compared with 149 during 1902 and 185 during 1901. In the Banswara State plague was indigenous at the commencement of the year, but by energetic measures and prompt evacuation of infected areas the spread of the disease was stopped, and from May until the end of the year the State was free from indigenous plague. In the Alwar State plague appeared in February, but was not reported until March. The State was free from the disease during July and August, but was re-infected from the Punjab in September. In the Mewar State 676 deaths from plague were recorded; in the Banswara State 648 deaths; in the Alwar State 420 deaths, and in Tonk 326 deaths. In Ajmer-Merwara 48 deaths from the disease were recorded.

Plague in Central India.—Plague commenced in Central India at the end of September, 1902, and continued with great severity throughout the year 1903, during which no fewer than 26,169 deaths from the disease were recorded as compared with only 408 in the previous year.

Plague in Mysore.—The total number of deaths recorded as due to plague in Mysore during 1903 was 20,223 as compared with 26,301 in 1902. Disinfection of clothing and houses with a solution of perchloride of mercury, and desiccation of houses by burning dried cowdung cakes in them, were the measures upon which most reliance was placed.

Plague in the Hyderabad State.—The total number of deaths recorded from plague in the Hyderabad State during 1903 was 28,094 as compared with 8,934 in 1902. The epidemic, which had prevailed during the previous year, attained its maximum intensity in February, 1903, and then quickly declined in severity, almost ceasing in June. In July, however, a recrudescence occurred, and the number of deaths recorded in December was almost equal to that recorded in February. The largest numbers of deaths were reported in the districts of Aurangabad, Bir, Usmanabad, and Lingsugar.

Fevers.

The total number of deaths recorded under the heading of fevers during 1903 was 4,459,237, or a ratio of 19.66 per 1,000 of population as compared with a total of 4,279,551 or a ratio of 19·17 during 1902. As in the previous year the increase in the mortality from fevers during 1903 was coincident with a very large increase in the prevalence of plague, and it is probable that many deaths from plague were returned as having been due to "fever." The year 1903 was, however, in all respects more unhealthy than 1902, and, although year by year it becomes more apparent that malarial fevers are a factor of less importance as a cause of death than has been generally supposed, it is not improbable that some portion of the increased mortality may have been due to an increase in the prevalence of malarial fevers. The greatest number of deaths from fevers was, as usual, recorded during the last three months of the year, but the excess in mortality during these three months was not nearly so great as might have been expected if malarial fever were the chief factor causing the deaths reported under the heading of fevers; and with the exception of these three months the largest number of deaths was recorded in June, the month during which malarial fevers are least prevalent over by far the greater part of the country. Some idea of the use that is made by village agencies

in Bengal of the heading "fevers" is given in the report of an enquiry carried out in the district of Dinajpur in Bengal by Captain Rogers, I.M.S. This officer sought out the relaives of 1,000 people whose deaths had been recorded by the reporting agents in villages of that district during 1903 under the heading "fever," and enquired from them the symptoms, course, and duration of the illness in case. He concluded that 318 of the deaths had been due to acute or chronic malarial fevers, 217 had been due to pneumonia, 90 to phthisis, 23 to bronchitis, 102 to diarrhœa, 18 to enteric fever, 61 to dysentery, 104 had occurred in infants who had been "born feeble," and 67 had been due to "other causes."

Table showing the deaths from Fever registered in British Provinces by Months during the year 1903.

PROVINCE.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	TOTAL. 1903.	RATIO OF DEATHS PER 1,000 OF POPULATION. 1903.
Bengal	141,131	119,626	146,400	138,130	130,800	130,847	121,133	127,209	129,744	129,560	168,794	171,567	1,654,941	22·23

In Bengal the death-rate from fevers during 1903 was 22·23 per 1,000 of population against 23·13 in 1902. The majority of deaths occurred in November and December, but a very large number were returned in March, coincident with the maximum period of plague mortality. The highest death-rate from fevers during the year was recorded in the district of Dinajpur, and after the close of the year Captain Rogers, I.M.S., was deputed to make a special enquiry into the cause of the great unhealthiness of this district. The results of that portion of his enquiry which referred to the incorrectness of the diagnoses made by reporting agents in villages have been briefly noted above. This part of his investigation occupied so much time that he was unable to do much microscopic work, but in the spleen blood of 30 cases suffering from fever and enlargement of the spleen he found malaria parasites in five and the parasites which are presumed to be the cause of *kala azar* in ten. The latter parasites have also been found as a cause of fever in other parts of Bengal. Some cases of so-called "Burdwan fever" have been shown by Captain James, I.M.S., to be of this nature and also some cases of fever occurring in Dacca. It would be of interest to ascertain whether the natives in Dinajpur and other districts of Bengal where a high mortality from fever is recorded, regard the dangerous fever from which they suffer as malarial fever or whether, like the natives of Assam, they regard it as so essentially different as to require a special name. In Assam the death-rate from fevers during 1903 was 14·22 per 1,000, as compared with 14·72 in 1902 and 15·86 in 1901. The total number of deaths recorded as due to *kala azar* in 1903 was 5,033. Since 1897 there has been a steady decrease in the number of deaths recorded year by year from this disease, but Captain James, I.M.S., who has lately made a tour of investigation in Assam, expresses the opinion that *kala azar* is much more prevalent than is generally thought to be the case. There is no very obvious reason why the death-rate from dysentery and diarrhœa in Assam should be so much higher than in Bengal, and it is possible that many deaths from *kala azar*, which frequently terminates with dysenteric symptoms, are returned under the heading of bowel complaints. The tables given by the provincial

Sanitary Commissioner show that while 5,033 deaths from *kala azar* were recorded, only 833 cases of the disease were treated in the dispensaries throughout the province. These figures indicate on the one hand either that the people have no faith in the treatment provided at the dispensaries in Assam, or on the other hand that the diagnoses made by reporting agents in districts, or those made at the dispensaries, are incorrect. All these factors are undoubtedly at work, but, in the light of recent knowledge, the erroneous diagnosis of cases treated at dispensaries is undoubtedly a chief factor to which the discrepancy between the number of cases treated in these institutions and the number of deaths recorded in districts, must be attributed. In a village within two miles of the Gauhati dispensary Captain James found that over 20 per cent. of the people were suffering from *kala azar*, but only eight cases of the disease had been recorded in the books of the Gauhati dispensary as having been treated during 1903. The disease was also found to be very prevalent in the areas adjoining the Tezpur and Mangaldai dispensaries, but only eight cases were recorded as having attended at the former dispensary during 1903 and only 18 at the latter.

The death-rate from fevers in the United Provinces during 1903 was higher than in any other province of India, and 3·14 per 1,000 higher than in 1902. Some of the increased mortality returned under this heading may have been due to plague and some to measles, which is said to have caused even more deaths than plague. The towns of Meerut and Farrukhabad, in which death-rates from "fevers" of 52·64 and 43·92 per 1,000, respectively, were returned, are reported by Captain James to be only slightly malarious, and there are reasons for thinking that a considerable number of the deaths recorded under the heading of fevers in these and other towns in the province were due to broncho-pneumonia, occurring perhaps as a complication of measles.

In the Punjab the death-rate from fevers during 1903 was 25·33 per 1,000 of population, as compared with 23·54 in 1902. There is no reason to doubt that in this province, at any rate, most of the deaths recorded as due to fevers are really due to malarial fever. The monthly rise and fall in the mortality from fevers corresponds very accurately with the known seasonal incidence of malarial fevers in this province, and the sudden great increase in mortality during October, November, and December, can scarcely be due to any other cause than malaria. Moreover, from the examination in the Punjab of a considerable number of cases of fever associated with great enlargement of the spleen, and sometimes of the liver, Captain James concludes that such cases occurring in the Punjab are malarial in origin, and are not the result of infection with the new parasite which in some other parts of India seems likely to prove to be such an important cause of death. In the North-West Frontier Province the death-rate from fevers during 1903 was 2·45 per 1,000 higher than during 1902. In the Central Provinces and Berar, 190,707 deaths from fevers were recorded during 1903, equal to a ratio of 15·27 per 1,000 of the population. With few exceptions in the districts of the Central Provinces in which plague prevailed, an increase in mortality from fevers was recorded during 1903, but in the Berar districts in which plague prevailed the recorded mortality from fevers was considerably reduced. In Lower Burma the death-rate from fevers was 1·28 per 1,000 higher than in 1902, and in Upper Burma fevers were also more prevalent during 1903 than during the previous year.

In the Madras Presidency the ratio was 8·4 per 1,000, against 7·65 per 1,000 in 1902. A death ratio of 12·3 per 1,000 was recorded in the town of Madras as compared with ratios of 14·7 in 1902 and 18·3 in 1901. The comparatively high death-rate from fevers annually recorded in Madras town has for several years been difficult of explanation except on the grounds of inaccurate diagnosis, for the theory which had so long prevailed that malarial fevers were very common and severe in Madras town was shown in 1902 to be incorrect. The explanation is now forthcoming in the discovery made by Major Donovan, I.M.S., that the cases of fever associated with enlargement of the spleen which are so common in Madras are really not cases of malaria at all, but are caused by the parasite discovered by Major Leishman. The disease is, in fact, identical with that which has been so long known to the natives of Assam under the term *kala azar*. In Bombay the mortality from fevers during 1903 declined somewhat, as compared with the previous year. Since 1897 the falling off in the number of deaths ascribed to fevers in Bombay has been remarkable. In the six years ending 1897 the aggregate number of recorded fever deaths was 2,432,935 while in the six years 1898-1903 the aggregate

was 1,810,581, a decline of 622,354; this is, no doubt, largely due to the decrease in the number of the total population, but the later six years includes the large total of 543,319 recorded in 1900, and it is evident that there has been considerable change in the classification of deaths by the reporting agencies. The total number of deaths in the six years ending with 1903 exceeds the total of the six years ending with 1897 by 1,143,318, the details showing a decline of 622,354 in the total number of deaths recorded as due to fever and of 1,254 in the total number of deaths ascribed to cholera, and increases of 1857 from small-pox, 761,233 from plague, 263,693 from dysentery and diarrhœa, 118,728 from respiratory diseases, 6,640 from injuries and 614,775 from other causes.

Anti-mosquito operations.—In Bengal steps were taken for the organisation by private enterprise of agencies for the destruction of mosquitoes, but the provincial Sanitary Commissioner remarks that, from the reports received, it appears very little was done, and that the people were very apathetic in the matter. A "mosquito brigade" consisting of ten men under the supervision of a Hospital Assistant was, however, formed in Puri town, and worked there for some months. No organised operations on a large scale were initiated in the United Provinces, but increased efforts were made in many localities to improve surface drainage, and to bring quinine more generally within the reach of the poorer classes. In the Punjab trial measures for the destruction of mosquitoes were initiated during the year in the towns of Gujranwala and Gujrat, but the severe prevalence of plague prevented their being carried out in a systematic way. In the Central Provinces it had been intended to carry out systematic operations during 1903 in five selected towns. In the town of Bhandara nothing special was done owing to want of funds. In Bilaspur nothing was done, pending the introduction of a drainage scheme, of which the town is badly in need. In Hoshangabad a special gang of coolies under the direction of the Civil Surgeon cleaned out pools and drains likely to become breeding places of mosquitoes during September, October and November, but little else appears to have been done. In Mandala the Municipal Committee placed three coolies at the disposal of the Civil Surgeon; a number of pits and pools were filled up, drains cleaned out and levelled and an effort made to prevent the destruction of fish in the river which waters the town. In Khandwa eight men worked under the Civil Surgeon's orders throughout the year. A large number of pits and hollows were filled up and pools periodically swept out. The use of kerosine oil was discontinued, as it was not found possible to direct the main expenditure of the oil in the proper direction. The plague epidemic of 1903 made it difficult to say whether the fever mortality of Khandwa was affected by the measures. The main dispensary returns showed a smaller attendance for malarial fevers than in 1902, but the general attendance was also less by reason of plague. In Madras the local Government has directed that funds be allotted by local bodies for experiments in six carefully selected areas, having for their object the extermination of malaria by the destruction of mosquito larvæ, minor engineering works and the administration of quinine. The officer selected for the duty will work under the office of the provincial Sanitary Commissioner, and will have attached to him an intelligent engineering subordinate.

Sale of Quinine.—In Bengal there was a considerable reduction in the number of packets of quinine sold during 1903, only 28,595 parcels (each containing 102 five grain packets) being disposed of as compared with 34,114 parcels in 1902. The reduction is considered to have been due to the lesser prevalence of fever during 1903 than during 1902.

In Assam the sale of quinine increased slightly during 1903, a total of 1,547 parcels, each containing 102 five grain packets, being disposed of, as compared with 1,434 parcels in 1902.

In the Central Provinces the sale of quinine showed a steady increase, 3,550 parcels, each containing 102 five grain packets, being sold, as compared with 2,681 in 1902. In Berar 3,321 parcels were sold, or 770 less than in 1902.

In the United Provinces 236,131 packets of quinine—137,463 being five grain packets and 98,668 seven grain packets—were sold in 1903 against 224,999 in 1902. Quinine was sold in post offices in all districts except Gonda, but it was sold by vaccinators only in 29 and by landlords in 12 districts. In the Punjab quinine was, as usual, gratuitously distributed during the year in a large number of districts

but no information regarding the sale of the drug is contained in the provincial Sanitary Commissioner's report.

In Burma 192,751 five grain packets of quinine were sold through the medium of post offices in 1903, as compared with 179,708 in the previous year. Quinine was also sold by vaccinators in villages, but the number of packets disposed of in this way during 1903 was only 230.

Details are wanting regarding quinine sales in the North-West Frontier Province, Madras, and Bombay.

Dysentery and Diarrhœa.

The number of deaths recorded under the heading of dysentery and diarrhœa rose from 235,750 in 1902 to 273,459 in 1903, and the death-rate per 1,000 of population from 1·06 to 1·21. The increased mortality was due chiefly to a severer prevalence of the diseases in the United Provinces, the Central Provinces, the Punjab, and the Madras Presidency. In Bengal, Assam, and the Bombay Presidency the mortality from dysentery and diarrhœa was the same during 1903 as during 1902, though the total number of deaths recorded during 1903 was slightly less. The districts in which the highest death-rates were recorded were Howrah, Darjeeling, Cuttack, Puri, Patna, Calcutta and Hoogly. The urban mortality was, as usual, much higher than the rural. In all the districts of Assam except Kamrup, Goalpara and Nowgong, the death-rates from dysentery and diarrhœa during 1903 were lower than during 1902, and the ratio for the province as a whole was considerably reduced. The provincial Sanitary Commissioner is of opinion that although some part of the higher mortality from dysentery and diarrhœa recorded among tea-garden coolies than among the general population is only apparent, being due to the fact that cases

of anæmia and other diseases are often returned by tea-garden hospital assistants under the heading of the symptoms (dysentery and diarrhœa) by which they are terminated, yet there is in reality a greater mortality from dysentery in tea gardens than elsewhere. In the United Provinces the death-rate from dysentery and diarrhœa during 1903 was considerably higher than during 1902. The urban death-rate was 2·38 per 1,000, and the rural ·73 per 1,000. The mortality in some districts was unusually high, notably in Garhwal, Almora, Fyzabad, Ballia and Unao. The recorded mortality from dysentery and diarrhœa in the Punjab was also increased. The greatest numbers of deaths were returned during the months when malarial fevers were most prevalent. The death-rates from dysentery and diarrhœa in all the districts of Berar and in nearly all the districts of the Central Provinces were considerably higher in 1903 than in 1902. The death-rate recorded in Berar was more

than three times as high as that recorded in the Central Provinces, and the month of maximum mortality was October in Berar and September in the Central Provinces. In Madras the death-rate from dysentery and diarrhœa was 1·3 per 1,000 in 1903, as compared with 1·01 per 1,000 in 1902. The death-rate in municipalities was four times as high as in rural areas. In Bombay the total number of deaths and the death-rate per 1,000 from dysentery and diarrhœa were somewhat reduced. The mean annual number of deaths returned under this heading during the six-year period since 1898 is more than double the mean annual number so returned during the six-year period from 1892 to 1897. In Lower Burma the death-rate from dysentery and diarrhœa in 1903 was 1·61 per 1,000 as compared with 1·30 in 1902, and in Upper Burma it was ·39 as compared with ·23. Cholera was prevalent in Upper Burma and some of the mortality recorded as due to dysentery and diarrhœa may have been due to this disease. In Ajmer-Merwara 455 deaths were attributed to dysentery and diarrhœa; and 137 in Coorg.

General History of Vaccination.

Vaccination in India.—The aggregate number of operations performed in 1903-04 by all public agencies in all the provinces was 8,457,298, against 8,431,564 in the preceding year, and 8,036,444 in 1901-02. In every province except Bengal, Assam, Madras and Coorg, there was an increase, which in most cases was limited to primary operations. The mean number of vaccinations performed by each vaccinator fell from 1,460 in 1902-03 to 1,458 in 1903-04, ranging from 2,635 in the Punjab to 880 in Ajmer-Merwara.

Primary operations totalled 7,916,262 against 7,791,858 in the preceding year, there being an increase in the number performed in every province except Assam, Madras and Coorg. In Assam where there was much less small-pox than in 1902-03, vaccination was impeded in Lakhimpur by the presence of measles, and there was a falling off in the work done on tea gardens in Cachar. In Madras the falling off is explained by the decrease in the prevalence of small-pox, by insufficient and irregular supplies of lymph in certain places, and by the absence of vaccinators. In Coorg, although small-pox was more prevalent than in the preceding year, some of the vaccination staff were employed on duties in connection with plague.

Revaccinations declined in number from 639,706 in 1902-03 to 541,036, the decline taking place in all the provinces except the Central Provinces and Berar, Burma and Ajmer-Merwara. In all provinces in which there was a falling off, except the United Provinces, the Punjab, the North-West Frontier Province and Coorg, small-pox was less prevalent than in the preceding year, and in all except the North-West Frontier Province plague was prevalent. The falling off in the number of revaccinations in the United Provinces was slight, but in the Punjab it was considerable and in the North-West Frontier Province very great. In the Punjab there was a great extension of the prevalence of plague, and it is stated that there has been a lack of system in the proceedings of the vaccinators, while a rule was introduced to prevent the repeated revaccinations of children for the purpose of swelling the returns. In the North-West Frontier Province the falling off seems to have been largely due to ill-health among the people and among the vaccinators.

The number of operations performed at dispensaries fell from 208,733 to 195,730, including 128,945 in Bengal, 21,078 in Assam, 16,106 in the Central Provinces and Berar, 13,930 in Burma and 12,854 in Madras; elsewhere dispensary vaccination was unimportant or non-existent.

The mean percentage of success in primary operations fell from 95.10 to 95.05, ranging from 99·17 in Ajmer-Merwara and 99·13 in the Punjab to 84·98 in Burma. The mean percentage of success in revaccinations also fell fractionally from 68·20 to 68·19, ranging from 88·21 in the United Provinces to 43·65 in Burma.

The mean proportion of the population successfully vaccinated rose from 33·14 per 1,000 in 1902-03 to 33·32 in 1903-04, ranging from 48·67 in Coorg and 44·28 in Assam, to 27·42 in Ajmer-Merwara and 24·63 in Bombay.

Estimating the birth-rate in each province at 40 per 1,000, the percentage of infants protected during the year rose from 39·15 in 1902-03 to 39·53, but the percentages in the provinces varied greatly, from 66·73 in the Central Provinces and Berar and 58·23 in the Punjab, to 26·29 in Assam, 19·0 in Burma and 11·63 in Coorg.

Preservation of calf lymph.—In this report for 1902 mention was made of the researches in the preservation of animal lymph by means of the admixture of

glycerine and of vaseline which had been carried out by Captain W. F. Harvey, I.M.S. Those researches have been extended, and at the suggestion of Lieutenant-Colonel Bamber, Sanitary Commissioner of the Punjab, experiments have been made on the use of chloroform as a purifier after the method described by Dr. A. B. Green. Those experiments have been most successful. It was found that the passage of the vapour of chloroform through lymph pulp suspended in sterile water, with or without the addition of glycerine, killed all except spore-bearing and very resistant bacteria, and that from three to six hours treatment with chloroform vapour was practically equal in purifying effect to treatment by means of glycerine for a month. It appears, however, that the purification effected by chloroform is similar in kind and degree to the purification effected by glycerine, the difference is in speed, and the advantage of the use of chloroform depends upon this. If lymph is preserved in glycerine and kept at a low temperature, deterioration of the vaccine virus is very slow, but the extraneous organisms do not die quickly. If the preserved lymph is kept at a high temperature, the extraneous organisms are soon killed, but the vaccine virus is injured. The preliminary treatment by chloroform vapour kills most of the extraneous organisms and the lymph can be kept in glycerine at a low temperature for a long time without losing its protective power. If the lymph is to be kept the addition of a preservative after the treatment with chloroform is necessary, otherwise those bacteria which have not been killed by the chloroform will multiply. Glycerine seems to be the best preservative, because, although it may not kill the organisms that chloroform has failed to kill, it prevents their multiplying.

It was found that:—

"(*a*) There is but little difference between lymph that has been glycerinated before and that which has been glycerinated after being chloroformed.

"(*b*) After chloroforming practically no further purification is effected by glycerine when lymph is kept at a low temperature.

"(*c*) Lymph which is glycerinated only and kept at a low temperature will become purified but slowly.

"(*d*) Lymph which has been chloroformed only and had no preservative added will show a great and rapid increase of micro-organisms at the end of a month even although kept at a low temperature."

Captain Harvey's further experiments show that glycerinated lymph is in all respects superior to vaselinated lymph.

Bengal.—The total number of persons vaccinated in Bengal during the season 1903-04 was 2,748,638, as compared with 2,781,972 in the preceding season. Of the total operations performed 2,634,563 were primary and 114,075 revaccinations, the corresponding figures in 1902-03 having been 2,592,177 and 189,795. There was, therefore, an increase of 42,386 primary operations and a decrease of 75,720 revaccinations, equal to a decrease of 33,344 in the total number of operations. The average number of operations performed by each vaccinator was 961, against 972 in 1902-03. The percentages of success claimed were 98·18 in primary operations and 66·40 in revaccinations, against 98·11 and 68·07, respectively, in the preceding season. In 28 of the 49 districts the numbers of operations increased, most notably in Faridpur 23,788, Mymensingh 14,355, Rangpur 14,347, Cuttack 12,264, all districts in which small-pox was much less fatal than in 1902-03. In the remaining districts the decrease in the numbers of operations was greatest in Midnapore 54,286, Dinajpur 17,561, Balasore 17,342, Manbhum 12,546, in all of which the small-pox mortality had largely declined. The falling off in the number of operations generally is attributed to the diminution in the prevalence of small-pox, the mortality from which fell from ·58 to ·33 per 1,000, to illness and misbehaviour of vaccinators, and the prevalence of malaria in some eastern districts, and of plague in the western districts. But the opinion of the Local Government is that the Department, as at present constituted, is unable to cope with the requirements of the province, and proposals for re-organising it and increasing the superior staff so as to secure adequate supervision are under consideration.

The vast majority of the operations, 2,006,716, were performed with human lymph; 212,537 were performed with calf lymph, and 415,310, an increase of 16,105 as compared with the previous season, with lanolinated lymph, the ratios of success claimed being with human lymph 98·35 per cent. as compared with 98·38 in 1902-03, with calf lymph 98·83, against 98·13, and with lanolinated lymph 97·01 against 96·75

Of the estimated number of children available, 29·36 per cent. were protected against 29·92 in the previous year; in fifteen districts the percentage protected was over 50, but in Tippera, Mymensingh, Midnapore, the Tributary States of Orissa, Puri, Noakhali, Cuttack and Balasore it was under 20. In municipal towns the number of children protected was 71·1 per cent. against 72·3 in 1902-03. The falling off in the percentage of children protected, which is calculated on a hypothetical birth-rate of 40 per 1,000 is, no doubt, in part due to a falling off in the number of births, of which 84,609 fewer were registered in 1903 than in 1902.

The quantity of lymph paste manufactured at the Calcutta depôt rose from 103,470 grains in 1902-03 to 130,680 grains, the demands from the districts, especially from Orissa, Faridpur and Backergange having increased. At Darjeeling the quantity manufactured increased by 1,488 grains to 49,189 grains, of which 515 and 630 grains were supplied to the Nepal Darbar and the Sikkim State, respectively.

Assam.—The total number of operations performed by all agencies in Assam in 1903-04 was 278,802, or 25,319 fewer than in the previous year, and 2,025 fewer than in 1901-02. Of the total 273,477 were primary operations with a percentage of success at the rate of 97·87, and 5,325 were revaccinations, of which 81·86 per cent. succeeded; in 1902-03 primary operations numbered 291,332 and revaccinations 12,789, the success claimed being 97·90 and 77·81 per cent. respectively. A falling off in the numbers of operations occurred in eight of the 13 districts, ascribed in Sylhet to a decline in the special activity induced by the prevalence of small-pox in 1902-03; in Lakkimpur to an outbreak of measles; in Nowgong to the absence of a vaccinator for four months; in the Naga Hills to a more careful check of the work of the operators, and in the Garo and Lushai Hills to the unwillingness of the people to be vaccinated in the absence of small-pox. The number of persons vaccinated by each vaccinator, excluding dispensary and tea gardens' agencies, averaged 988 against 999 in the preceding season.

Estimating the number of infants available at 40 per thousand of the population, 26·29 per cent. were protected during the year. In the municipal towns where the number of available children is deduced by deducting the number of recorded deaths from the number of registered births, a mean of 67·77 per cent. were protected, the figures varying between 85·71 in the Union of Golaghat and 39·41 in Gauhati.

At the vaccine depôt 429,080 tubes of lymph were obtained from 444 calves, an average of 966·39 per calf, and were distributed throughout the province. Complaints were received regarding the quality of certain early supplies, which it seems probable were kept too long before use.

United Provinces.—In spite of the continued increase of plague, the number of vaccinations rose from 1,665,253 in 1902-03, to 1,667,104 in 1903-04. The increase was in the number of primary operations which rose from 1,562,070 to 1,564,469, while the number of revaccinations fell from 103,183 to 102,635, the percentages of success being 97·83 and 88·21, against 97·90 and 88·41, respectively. In 28 districts, including the native State of Tehri-Garhwal there was an increase in the number of successful primary operations, and in 21 there was a decrease, due in the cases in which the falling off was greatest to the presence of plague. The average number of persons vaccinated by each vaccinator was 1,837, as compared with 1,840 in the previous year. Of the number of children in the province estimated as available, 50·33 were successfully vaccinated; in municipalities the percentage of available children protected was 98·2, but this figure is raised by the inclusion in the calculation of children brought from the district into the town to be vaccinated.

Bovine lymph depôts were maintained at Lucknow, Allahabad, and Bahraich, and, owing to an outbreak of small-pox in certain of the plains districts, a temporary depôt was opened at Naini Tal. The construction of the new central depôt at Patwa Dangar in the Naini Tal district was nearing completion.

Punjab.—The total number of vaccinations performed by all agencies in the Punjab in 1903-04 was 685,105 as compared with 667,544 in the preceding year. Of the total, 604,204 were primary operations, an increase of 21,578 on the total of 1902-03; but there was a further decline in revaccinations, which numbered only 80,901, or 4,017 less than in the preceding year. The increase in the number of primary operations shows that, in spite of the extended prevalence of plague, ground is being regained. The fall in the number of revacci-

nations it attributed by the provincial Sanitary Commissioner to the prevention of the revaccination of children who have been vaccinated or revaccinated only a few years before, and by the local Government to the lack of system on the part of vaccinators. The percentage of success in primary operations was 99·13, and in revaccinations 76·25, this considerable improvement on the results of the preceding year being in part at any rate due to the exclusion from the calculation of cases in which results were not known. Of the primary operations, 53 per cent. were performed on males and 47 per cent. on females (a proportion which happens to be almost exactly that of the distribution of the sexes in the total population), while of the revaccinations 62 per cent. were performed on males and only 38 per cent. upon females, because, it is explained, parents are reluctant to allow their young daughters to be seen by the vaccinators.

No town was brought under the Act during the year, but in most of the towns in which it is in force the work performed was satisfactory. In some towns no operations were performed on account of the severity of plague.

The numbers of primary operations and revaccinations performed in Patiala were 44,500 and 6,219, respectively; in Bahawalpur, 17,379 and 21; in Kapurthala, 5,699 and 40; in Faridkot, 4,913 and 1,401; and in Jhind, 4,751 and 1. The percentages of success ranged in primary cases from 99·50 in Patiala to 94·91 in Bahawalpur, and in revaccinations from 93·51 in Faridkot to 33·33 in Bahawalpur.

North-West Frontier Province.—The total number of vaccinations performed in the North-West Frontier Province, including the political agencies, was 99,176, an increase of 8,883 over the total of 1902-03, but the increase was due to a gratifying extension of the operations of the Department in Chitral where, small-pox being epidemic, no less than 28,353 vaccinations were performed; in the British districts, owing largely to the prevalence of sickness among children and illness of vaccinators, there was a great falling off. Primary operations numbered 94,262, nearly twelve thousand more than in the preceding season, but the number of revaccinations fell off by 3,027, success being at the rates of 91·52 and 79·91 per cent., against 93·54 and 69·84 in the previous season. The mean number of operations performed by each vaccinator was 2,609·90. In only two of the municipal towns, Bannu and Dera Ismail Khan, is the Vaccination Act in force, and the percentage of available children belonging to these towns who were vaccinated was 87·3.

Central Provinces and Berar.—The control of the Vaccination Department of Berar was transferred to the Sanitary Commissioner of the Central Provinces on the 1st November, 1903; as a consequence the arrangement under which in the Central Provinces Civil Surgeons are directly responsible for vaccination in their districts, was extended to Berar, and a scheme for the reorganisation of the combined department submitted to the local Administration.

The total number of operations performed in the Central Provinces, including the Feudatory States, during the year was 522,609, an increase of 58,558, which, in view of the wide distribution of plague, must be regarded as highly satisfactory. The percentage of success attained in 446,411 primary operations was 98·65, and in 76,198 revaccinations 87·74, against percentages of 97·13 and 85·14 in the same classes of cases in 1902-03.

In Berar, the number of operations fell from 141,064 to 123,696, but the percentage of success in primary operations which numbered 101,401, was 97·92 against 96·8 in 1902-03, although the rate of success in 22,295 revaccinations fell from 16·5 to 15·60. The decrease in the number of operations in Berar is attributed in part to the epidemic of plague and in part to the temporary breakdown of the depôt at Amraoti. The mean number of operations performed by each vaccinator was 1,815 in the Central Provinces and 3,255 in Berar. The difference in the degree of success claimed in revaccination in the Central Provinces and Berar is very striking, the percentages ranging in the former province from 100·0 in Saugor to 36·11 in Nimar, and in the latter from 23·90 in Buldana to 5·84 in Ellichpur. The cause of the difference is probably in part due to a higher standard being required in Berar, but the subject was under enquiry.

In the Central Provinces, 160,190 persons were vaccinated with fresh calf lymph and in 95·5 per cent. the operation was successful; 209,929 were vaccinated with glycerinated calf lymph with the same proportion of success; 1,076 were vaccinated

with lanolinated lymph, 92·6 per cent. successfully, and 32,669 with human lymph which gave the best results of all, 96·7 per cent. of success.

No new town was brought under the operation of the Vaccination Act, and in many of the municipalities vaccination is very backward.

Madras.—The total number of vaccinations performed by all agencies in Madras fell from 1,332,209 in 1902-03 to 1,309,985; primary operations falling from 1,250,762 to 1,240,655, and revaccinations from 81,447 to 69,330, the percentages of success in each class of operation being 89·02 and 68·95 in 1903-04, against 89·08 and 68·91 in 1902-03. The causes of the falling off, which occurred mainly in local fund areas, is stated to have been in various places the absence of small-pox, deficient and irregular supply of lymph, the prevalence of plague and absence of vaccinators. The number of operations performed by each vaccinator averaged 1,529.

Of the various lymphs in use during the year in primary operations the highest percentage of success, 98·5, was obtained with fresh calf lymph, followed by 96·9 with fresh calf lymph transferred for short distances in tubes and on plates. Lanolinated lymph from Bangalore gave a percentage of success of 95·0, whereas the locally prepared lanoline lymph succeeded in only 87·0, and glycerinated lymph in 86·9 per cent. For some reason the ratios of success in municipalities were higher than in local fund areas, in the former Bangalore lanolinated lymph succeeded at the rate of 96·5 per cent., locally prepared lanolinated lymph at the rate of 95·5 and locally prepared glycerinated lymph at the rate of 95·8. It is hoped that in the near future the full requirements of the Presidency will be derived from the King Institute at Guindy.

Coorg.—The total number of operations performed in Coorg fell from 11,407 in 1902-03 to 9,653. Of the total, 8,052 were primary operations, of which 93·47 per cent. were successful against 94·8 in the previous year; revaccinations succeeded at the rate of 79·13 against 80·4.

Bombay.—The number of operations in the Bombay Presidency in 1903-04 was 587,933, as compared with 578,885 in 1902-03, the increase being in the primary cases which rose from 537,744 to 552,101, while revaccinations declined from 41,141 to 35,832. The causes of the falling off are the presence of plague, the absence of epidemic small-pox, sickness or misbehaviour of vaccinators, &c. The percentage of success in primary operations was 92·51, and in revaccinations 55·02, as compared with percentages of 92·92 and 55·72 in 1902-03. Of the primary operations, 51·19 were performed on males, but of the revaccinations the percentage performed on males was 76·89, and on females only 23·11. The average number of operations performed by each vaccinator rose from 1,354 in 1902 to 1,377.

In the Presidency Circle practically only bovine lymph was used—fresh lymph apparently in most of the cases. In all registration districts except Gujarat, a proportion of the vaccination was performed with bovine lymph, but in the Presidency generally, human lymph continues to be used in the vast majority of the cases. A scheme for the establishment of a central depôt at Belgaum for the manufacture of preserved lymph for the whole Presidency is stated to have been under consideration.

Burma.—The total number of operations performed in Burma in 1903-04 was 412,564, an increase of 30,791 on the total of the previous year. The increase was almost entirely in primary operations, the number of which rose by 30,093 to a total of 384,722, but the percentages of success fell from 86·93 in primary operations to 84·98, and in revaccinations from 48·15 to 43·65. The mean number of operations performed by each vaccinator was 1,780 as compared with 1,739 in the previous year. The increase was pretty generally distributed throughout the province, except in the Mandalay division, in which there was a falling off in every district save Katha and in the Chin Hills. In municipalities, where the Vaccination Act is in force, 86·93 per cent. of the available infants were protected during the year. In Rangoon, where the amount of work done has greatly increased, 65 per cent. of the available infants were protected.

Lanoline lymph paste was supplied from the depôt at Meiktila, but results were not uniform, probably on account of varying skill on the part of vaccinators and to exposure of some consignments of lymph to the sun.

Ajmer-Merwara.—The number of operations performed in Ajmer-Merwara further increased from 12,992 in 1902-03 to 13,199 in 1903-04. Of the total, 13,111 were primary operations and 88 revaccinations, with success at the rates of 99·17 and 82·95 per cent. against 99·18 and 86·36 in 1902-03.

Civil Sanitary Works.

Bengal.—Excluding Calcutta and including the two new municipalities of Dumka and Nawabgunj, there were 159 municipalities in Bengal during 1902-03, as compared with 157 during the previous year. As, however, no statistics are available for the two new municipalities the figures below refer to the 157 municipalities which were in existence throughout the year 1902-03. Including an opening balance of £42,216 their total income amounted to £372,242, of which 43·01 per cent. was spent on sanitary works, original and recurring, 9·56 per cent. on roads, 5·40 per cent. on public safety, and 27·09 per cent. on all other requirements, the corresponding figures for 1901-02 having been 43·41, 9·89, 5·58, and 29·32, respectively.

The total expenditure on sanitary works amounted to £159,949 or 43·01 per cent. of income, as compared with an expenditure of £150,300, or 43·41 per cent. of income in the previous year. About £81,700 were spent on conservancy, over £23,700 on water-supply, over £10,000 on drainage, and nearly £33,300 under the heading of treatment of the sick. Compared with the previous year £7,739 more was spent on water-supply and £4,794 more on the treatment of the sick, while £1,334 less was spent on conservancy and £288 less on drainage. The increased expenditure on water-supply was chiefly due to large outlay by the municipalities of Darjeeling and Garden Reach. The new water-supply scheme for the former place is in progress, but has not yet been completed. The filtered water-supply from the Calcutta mains has been extended to the latter municipality, which is now being supplied daily with about 50,000 gallons of pure water. New dispensary buildings were constructed at Patna, Rampur Boalia, Jalpaiguri, and Serajganj, and the cost of these, together with £3,800 spent on the Bankipore hospital during the year, were mainly responsible for the increased expenditure under the heading of treatment of the sick. Only nine municipalities, or one less than in the previous year, spent over 10 per cent. of their income on original sanitary works, 20 against 17 spent between 5 and 10 per cent., 77 against 74 spent below 5 per cent., while 51 against 56 spent nothing on this account.

The total cost of various new works carried out by municipalities, district boards, Government, and private individuals, either completed or in progress, amounted in towns to £25,670 against £21,907 in the previous year, and in rural areas to £42,612 against £48,140. With the exception of the extension of the filtered water-supply from the Calcutta mains to the Garden Reach municipality, no new work of first class importance was either commenced or finished during the year.

The useful scheme inaugurated by the Patna Sadar Local Board for the improvement of sanitation in villages and rural towns continued to work satisfactorily, 112 villages being cleansed during 1902-03 by the Patna Sadar and Dinapore Local Boards at a cost of only £91. Under this scheme members of the Board report the names of villages in the vicinity of their places of abode which they find to be in an insanitary state. A list of such villages, together with an estimate for cleansing them, is then laid before the Local Board, and, when passed, cleansing operations are started under the supervision of a member of the Board. The work is carried out on a systematic plan and consists chiefly in the removal of filth and rank vegetation, and the filling up of ditches and hollows.

Four meetings of the Sanitary Board were held during the year and the usual consultation work was carried on by circulating the files to the members. The principal subjects discussed at the meetings of the Board were the efficiency of the septic tank system of sewage disposal and the question of the supply of filtered water to riparian municipalities from the mills within their jurisdiction. The provincial Sanitary Commissioner does not state whether any conclusions were arrived at as a result of these discussions. Preliminary estimates were prepared under the orders of the Board during the year for the supply of filtered water to the Barisal municipality and for the re-modelling of the Dacca water-works.

Detailed estimates of cost for the construction of septic tank latrines in the municipalities of Howrah, Dacca, Garden Reach, and Cossipore-Chitpur were prepared in the Board's office, and similar estimates of cost of the drainage schemes for the municipalities of Bihar and Uttarpara were prepared under the supervision of the Sanitary Engineer.

Plans and estimates were considered and opinions given regarding ten water-supply and drainage schemes, among them being certain improvements in connection with the Howrah water-works; a scheme for the supply of filtered water to the Titaghar municipality, the filtered water to be supplied by the owners of certain mills in the neighbourhood; similar schemes for the supply of filtered water to the Garulia and Bhatpara municipalities; and drainage schemes for Howrah, Rangpur, Barnagore and Naihati. The Board dealt also with a number of miscellaneous references made to them by Government and by local authorities. During the year the Sanitary Engineer inspected the water-works at Arrah, Bhagalpur, Burdwan, Berhampore, Dacca, Darjeeling, Howrah and Mymensingh, as also the drainage systems of Patna and Monghyr. In addition visits were made to Barisal, Buxar, Garden Reach, Baranagar and Sodepore either for the inspection of water-works, sanitary works or in connection with sewage disposal works.

During the year two Bachelor of Engineering students completed their term of practical training under the Sanitary Engineer and obtained certificates. Two other students with the same qualification have placed themselves under the Sanitary Engineer for training.

Assam.—Excluding four small towns which have no separate income, the total income of the municipalities, stations, unions, and towns in Assam during 1903 was £15,780, as compared with £14,530 in 1902. The expenditure on direct sanitation, which excludes £3,844 spent on roads and bridges, was £8,475, or 53 per cent. of the total income.

Under conservancy £4,864 was spent against £4,656 in 1902; under water-supply £1,286 against £1,836; under drainage £739 against £640, while the balance was spent on minor sanitary works (£1,406) and vaccination (£172). The proportion of income spent by local bodies on sanitation ranged from 85·78 per cent. in the Golaghat union, to 15·26 per cent. in the town of Lakhimpur. The principal sanitary improvements effected by local Boards in rural areas during the year were the construction and repair of tanks, wells, market-sheds and latrines, and the improvement of village sites.

No meeting of the Sanitary Board was held during the year. The provincial Sanitary Commissioner was consulted unofficially on all matters relating to sanitation, and during the touring season he inspected the sanitary condition of all head-quarter stations and nearly all sub-divisional towns, placing on record criticisms for guidance.

United Provinces.—No details regarding municipal or district board income, or of the expenditure on sanitation, are furnished in the provincial report. Many sanitary improvements in various directions were effected during the year under report, and the cost of the projects for improving the sanitary conditions of municipalities approved by the Sanitary Board amounted to £84,327, or 16 per cent. more than the corresponding figure in the previous year, and 75 per cent. more than in 1901. Projects for improving the drainage in Agra, Farrukhabad, Allahabad, Muzaffarnagar, Aligarh, Deoband, Mirzapur, Dehra Dun, Saharanpur, Fyzabad, Kosi, Pilibhit, Chandausi and Sitapur were either in progress or will be put in hand shortly. The work at Benares and Cawnpore is being carried on, while the important drainage scheme for Lucknow has now been started and is well in hand. The local Government has adopted, as part of their programme of plague prevention, an active sanitary policy, and in the spring of the year under review a grant of two lakhs of rupees was made for the general cleaning up and sanitary improvement of small municipalities and towns. A further grant of £4,000 was also made for the improvement of wells in the smaller centres of population, while the important sanatoria of Naini Tal and Mussoorie were assisted by allotments of £2,667 and £3,334, respectively, for the improvement of the general sanitary condition in the former station and that of the Landour bazaar in the latter. In addition to this the local Government proposes from 1904, to relieve municipalities of police charges to the extent of over three and a half lakhs and will grant one lakh for cleaning up certain towns and larger villages. The liberality of the local Government has

resulted in valuable work having been done already and is creating an interest in sanitation among the people.

The amounts of filtered water supplied per head of population in the towns in which water-works are in operation were as follows: at Benares over 15 gallons per head *per diem;* at Lucknow 5·5 gallons; at Cawnpore over 14 gallons; at Agra over 9 gallons; at Meerut over 4 gallons; at Dehra over 7 gallons; at Mussoorie over 6 gallons; and at Naini Tal 7 gallons. The results of analyses of the filtered water were, in nearly all cases, satisfactory.

Seven meetings of the Sanitary Board were held during the year, at which projects and estimates amounting to £84,327 for improving the sanitary condition of municipalities were considered, discussed, and approved. In connection with water-works the Board approved the plans and estimates amounting to £2,134 for the extension of the clear-water reservoir at Agra as well as other minor improvements in the water-works at Benares, Lucknow and Cawnpore. A project to cost £844 for improving the water-supply at Almora was also discussed. In all 27 drainage and sewerage schemes were considered and approved. Of these ten were in connexion with the surface drainage, latrines and sewers of Benares, the estimates for these schemes amount to £35,891. Other important drainage projects were those of Mirzapur (£21,630), Dehra Dun (£2,700), Kosi (£2,957) and Farrukhabad (£1,647). Plans and estimates for constructing slaughterhouses in Allahabad, Chandpur and Amroha were considered and approved, and among other miscellaneous works a project for constructing a vegetable market and a meat market at Bareilly (£4,370) received the Board's approval and recommendation for sanction.

Punjab:—No details of municipal income or of the expenditure on sanitary works are furnished by the Sanitary Commissioner of the Punjab in his report for the year under review.

The Sanitary Engineer gives, as usual, an interesting report of works in progress during the year. The Amritsar waterworks, estimated to cost £70,000, are well in hand, and of the forty wells to be sunk, twenty-two were completed to the full depth of 65 feet during the year. Five more were nearing completion and work on the remainder was well advanced. About two-thirds of the entire work of pipe-laying had been completed, and work on the city service reservoirs was progressing favourably. The construction of soil depôts in connexion with the Simla sewerage extension works, which are estimated to cost £34,575, was completed during the year, and the main system of new sewers on the south slope of the hill, leading to the Lalpani outfall, was in regular use throughout the year. Experiments in connexion with the biological treatment of sewage were continued. The septic tank at Lalpani continued to work satisfactorily, but the filter did not give good results. The Kasumpti experimental installation was brought into use in February. The septic tank did not work satisfactorily at first, but after the grit chambers had been reduced in length the results were better, and at the end of the year the tank was working fairly well. As at Lalpani the filters in this installation frequently become clogged and the effluent turbid and offensive. The effect of running septic tank effluent down a long flight of steps in order to thoroughly aërate it was tried. The steps were about eight inches each, and the total height of the flight was thirty-five feet. The effluent was deodorised to a considerable extent by this means, but analysis did not show any appreciable reduction of albumenoid ammonia or increase of nitrates. As the septic tanks have so far given good results it has been decided to install them at once at all the outfalls and to continue experiments with the filters. The Simla bazaar drainage works, estimated to cost £6,154, were completed during the year and have effected considerable sanitary improvement in the crowded bazaars of Simla. In connexion with the proposed extension of the Simla water-works, further information regarding sources of water-supply was collected and some surveys made. Umballa city suffered from shortness of water in the hot weather and works were commenced to augment the supply by adding four more wells to the head works. As the experimental aermotor pump at these works has worked satisfactorily the local Government has sanctioned the trial of two similar pumps at the new civil station of Mianwali. The extension of the trench wells for the Lahore water-works was completed during the year and the old wells were dredged and cleaned, thus substantially increasing the supply. The extension of the distribution system in the city and civil station at an estimated cost of £16,120 was proceeded with by the municipal committee and nearly completed.

Among the sanitary works under construction by the Public Works Department were the Lyallpur water-works, the estimated cost of which was £8,572, the Lyallpur drainage works estimated to cost £5,273, extramural drains for Umballa city estimated to cost £2,876, a sewer in Chandni Chowk at Delhi estimated to cost £1,722, the Toba Tek Singh drainage scheme estimated to cost £6,030, and the Gojra drainage scheme estimated to cost £4,160. All except the last of these works were completed, or nearly so, during the year under review. The experiment for raising water from a deep tube well by means of an air lift, referred to in last year's report, was carried through, but the result was not favourable, and tended to show that this method of raising water is not suitable for places where the subsoil consists of fine or moderately coarse sand.

Special efforts were made during the year to encourage the use of sewage at outfalls for land irrigation. The result in respect of sewage farms has not, so far, been encouraging, but a beginning has been made and success depends on the recognition given to the matter by local bodies.

The scheme for the grant of rewards and *khillats* to village communities to promote sanitation has not been attended with success. The Sanitary Commissioner himself is of opinion that small rewards are useless and that the payment of a sum of Rs. 500 into the *malba* fund of a village would possibly do more good.

Six meetings of the Sanitary Board were held during the year. The drainage schemes of Sangla, Sargoda, Ferozepore, Rawalpindi and Multan, as well as the water-supply scheme for Mianwali were considered and approved. The Board recommended to the municipal committee of Umballa that they should take up a piece of land for a sewage farm, and in connexion with the sewage disposal works at Simla they recommended the continuance of the filter experiments in the hope that they might throw light upon the method of disposal of the sewage at the Snowdon outfall. The land required for the sewage farms lies in State territory, and would have to be acquired by negotiations with the State authorities. Grants-in-aid for sanitary works were made to various local bodies out of the amount placed by the local Government at the disposal of the Board for this purpose, and the Board also allotted certain grants for experimental works at Umballa and Simla. The attention of the Board was also directed to the question of rewards to villages in the Chenab Colony for sanitary improvements and to other matters.

North-West Frontier Province.—The aggregate income in 1903 of the ten municipal towns and the Tank "notified area" in the North-West Frontier Province amounted to £46,470, the opening balance at the beginning of the year being £12,508. The expenditure on sanitary works was £9,236, equal to 19·8 per cent. of the income. It was incurred under the following main headings, the figures in brackets representing the expenditure under the same heading during 1902: conservancy establishment £4,472 (£4,461); paving £622 (£622); roads and bridges £458 (£1,022); drains and sewers £1,188 (£1,011); water-supply including cleaning wells and tanks £1,536 (£1,477); construction of latrines £142 (£76); repairs to latrines £22 (£32); widening streets £766 (£60).

The income derived from the sale of manure and street sweepings in all the municipal towns was £1,304 or £208 more than in 1902.

No new work of capital importance was undertaken during the year, but in Peshawar city the sum of £874 was spent on the extension of the water-supply, cleaning wells, and the maintenance of the water-works establishment, and the sum of £990 on the construction of new surface drains and the repair of old ones. In Kohat, in consequence of the limited quantity of pipe water available, it was possible to extend the supply only to the new slaughter-houses at Jarwanda and to Sangeri. In this town fair progress has been made of late years in the construction of town drains, and in 1903 the sum of £172 was spent on this account. In Dera Ismail Khan, Bannu, and other places in the province attention was paid to water-supply by the construction of new wells or water-cuts, and the cleaning out of old wells and tanks.

No rewards were paid or *khillats* given to village communities during the year for special interest taken in sanitary improvements, and, so far, no useful result is said to have followed the issue of sanitary note books to villages.

Central Provinces and Berar.—The sanitary administration of Berar was taken over by the Sanitary Commissioner of the Central Provinces on the 1st of November, 1903; and in future a single report on the combined area will be given.

In the Central Provinces the total income of head-quarter municipalities during 1902-1903, excluding opening balances and receipts under the heading of "Grants and Contributions for General and Special purposes" and "Extraordinary and Debt," amounted to £70,897, or £2,136 less than in the previous year. Of this sum 35·76 per cent. was spent on original and recurring sanitary works, 7·77 per cent. on medical relief, ·08 per cent. on vaccination, and 2·10 per cent. on other sanitary requirements.

In Berar the total income amounted to £12,367, of which 33·84 per cent. was spent on sanitary works, ·49 per cent. on vaccination and 3·07 per cent. on other sanitary requirements.

No new work of great importance was undertaken during the year, but in connexion with the Nagpur water-works a sum of £3,795 was expended in laying a duplicate rising main and in providing a new pump; the Nagpur drainage survey was also completed and the project prepared. Extensions of the water-supply service were made in connexion with the Bhandara, Harda, and Burhanpur water-works, and drainage surveys for Khandwa and Burhanpur have been completed. A number of minor works were carried out by municipalities chiefly in connexion with the improvement and extension of water-supplies and the construction and repair of drains. In the villages of the Central Provinces which are under the Village Sanitation Act, the chief expenditure was incurred under the headings of conservancy and clearing of village sites. The provincial Sanitary Commissioner considers it desirable that in all these villages a certain portion of the income should be devoted to improvement of the water-supply and of the drainage, and notes that in the districts of Bhandara and Wardha only does this appear to have been done to any appreciable extent. In comparison with the previous year considerable activity has been shown in sanitary matters in several head-quarter municipalities in the Central Provinces.

During the year a special grant of £1,667 was made by the local Government for the improvement of village water-supply in the Central Provinces. The money was allotted to villages in the Nagpur, Chhattisgarh, Jubbulpore and Nerbudda divisions, and the works as finally sanctioned were the construction of 95 new wells, the repair of 80 existing wells, and the construction and improvement of five tanks, at a total estimated cost of £3,000. It is expected that all these works will be completed before the onset of the rains of 1904.

During the year meetings of the Sanitary Board were held at the head-quarters of all districts in the Central Provinces, except Seoni and Nagpur. Steps have been taken to maintain in each district council's office a record of desirable works of village sanitary improvements as well as a register of all wells constructed in connexion with the district sanitary schemes, with a view to their being periodically inspected and kept in good repair. The work done under the direction of the Board was chiefly in connexion with the construction and repair of wells.

In Berar the meetings of the Sanitary Board have hitherto usually been held at district head-quarters during the rains. There is nothing in the nature of a district sanitary scheme and proposals for sanitary improvements have usually been made by the Sanitary Commissioner, the entire cost being debited to district funds. Apparently no local aid has ever been sought. In future the Civil Surgeons of Berar, like those of the Central Provinces, will go on tour during the cold weather in order that they may become acquainted with the sanitary needs of their districts.

Madras.—No details regarding income or expenditure of municipalities are furnished in the provincial report. The Cocanada water-works, the estimate for which amounted to £31,080, and the Vizagapatam water-works were both completed during the year and opened for public supply. The protective works to the head-works of the Trichinopoly water-works were also completed during the year and two additional infiltration wells for these works were sunk. Water-works for Coonoor, Guntur and Dindigul were in course of construction and good progress had been made with them by the end of the year. The construction of experimental filters for disposal of the sewage from the King Institute of Preventive Medicine at Guindy was completed by the Sanitary Engineer.

Schemes in connexion with water-supplies for Coimbatore, Gudiyattam, Nellore, Cuddapah, Ellore, Kodikanal, Masulipatam, Tiruvannamalai, Vellore and Saidapet were considered and dealt with, as well as schemes of drainage for Ootacamund, Anantapur, Madura, Mangalore, Srirangam and Salem.

The plans and estimates for 101 minor sanitary works, of which three were minor drainage works, 31 minor water-works, 29 hospitals, 20 markets, 10 slaughter-houses, 4 latrines, 1 incinerator and 3 improvements to roads and buildings, were checked and scrutinised by the Sanitary Engineer during the year.

Slow but steady improvement is being made in the conservancy of towns, and there is evidence that the utility of night-soil for agricultural purposes, notwithstanding caste prejudices, is year by year more fully recognised. Thus, during 1902-03 municipalities realized the sum of £2,806 from the disposal of rubbish and night-soil as compared with £2,788 in the previous year, and £1,518 during 1892-93. In Tanjore the net profit from sewage farming was £125, and in Madras City it amounted to £2,402. Modified filter trenches, to replace cesspools, have been introduced with success in Cuddalore, Palamcottah and Periyakulam.

The total income of District Boards during 1902-03 amounted to £643,817, of which, if the total income after meeting "plague charges" be regarded as that solely available, only 5·4 per cent. was spent on sanitation. The provincial Sanitary Commissioner is of opinion that the absence of new sanitary works carried out by district boards is partly due to a lack of officers with time to devote to suggesting and drawing up the main outlines of simple schemes, and in this respect improvement may be expected from the recent appointment by the local Government of District Health Officers of the Assistant Surgeon class.

During the year the Sanitary Board reviewed the schemes relating to 149 sanitary works, of which 50 were for municipalities, 94 for Local Fund Boards, 1 for the Collector of Madura, 1 for the Collector of Salem, 1 for the District Magistrate of Anantapur, and 2 for the Inspector-General of Prisons, the aggregate estimated cost of the schemes being £117,760.

The following were among the more important schemes reviewed:—

(1) The water-supplies of Vellore (£24,000), Yercaud (£4,947) and Kodaikanal (£4,150).
(2) The drainage of Madura (£43,826) and Ootacamund.
(3) Improvements in the sanitation of Ootacamund (£964).
(4) Hospitals at Nandyal (£3,667) and Bezwada (£3,904) and a dispensary at Tirukkattuppalli (£334).
(5) Improvements to the market at Coonoor (£12,467) and a general market at Calicut (£2,020).

Rules for the conduct of the business of the Board were revised and the effect will be to reduce the volume of work devolving on the Board and secure greater expedition in carrying out smaller schemes. In future the powers of sanction of local bodies will be up to £34 and schemes costing between £34 and £67 will be disposed of by the Sanitary Engineer without reference to the Sanitary Board.

Coorg.—Particulars regarding the income and expenditure on sanitation of the municipal towns or of the district boards are not given in the provincial report. The advent of plague directed special attention to sanitation throughout the province and gave rise to a total expenditure of £312, but apart from the permanent improvements effected by a portion of this outlay, no sanitary work of importance was carried out during the year.

No formal meeting of the Sanitary Board was held during the year, but the Commissioner and the Civil Surgeon met frequently to discuss the details of certain sanitary reforms carried out in Mercara and Virajendrapet.

Bombay.—Excluding the Presidency town there were 166 municipalities in Bombay during the year 1902-03; and their aggregate income amounted to £398,960. Out of this sum £106,042 were spent on improving water-supply, on drainage and on conservancy within municipal limits. Compared with the previous year there was a decrease of about 4 per cent. in income and an increase of about 12 per cent. in expenditure.

The ravages of plague have embarrassed the financial position of most municipalities and for want of funds many urgent schemes of water-supply and drainage have not been carried out. At Ahmedabad the extension of the drainage, estimated to cost about eleven lakhs of rupees, made good progress during the year. The Sanitary Engineers inspected the works twice during the year and advised regarding a site for the proposed sewage farm. The municipality of Karachi applied for permission to raise a loan for the extension of the drainage, estimated to cost about eleven and a half lakhs of rupees, and the Sanitary Engineers submitted a report upon the scheme.

The income of the local Boards during the year amounted to £326,463, of which £15,718 were spent on water-supply and drainage. As compared with the previous year the income of these Boards increased by £30,540, and the expenditure under the above heads by £4,974.

The Bombay Village Sanitation Act of 1889 was in force in 265 villages against 294 up to the end of last year, the decrease being due to the abolition of 37 non-working committees in the Poona collectorate.

Sanitary inspection books have been introduced into a large number of towns and villages, and in Broach they have been introduced throughout the district.

The Sanitary Board met once only during the year, when a number of minor questions were discussed and a recommendation was made that two surveyors should be appointed to work under the Sanitary Engineer for the purpose of preparing small projects for municipalities. The only important question referred for the opinion of the Board was that of the sanitary regulations to be adopted for the new suburbs of Bombay in the island of Salsette. The work of locating the proposed roads, open spaces, building sites, &c., of these suburbs is being carried out under the orders of the Collector, and the Sanitary Engineer visited the locality three times during the year.

The following were some of the schemes upon which the advice of the Sanitary Engineer was requested :—

(1) The water-supplies of Tatta, Poona, Sukkur, Bhiwndi, Karachi Jail and Ahmedabad;
(2) The drainage schemes of Sholapur and Malabar Hill;
(3) Sites for police lines at Poona, and for a jail at Nasik.

The experiments on the Manjri experimental sewage farm are being continued.

Burma.—The aggregate income of the 41 municipalities in Burma during 1903, including opening balances, amounted to £655,092 against £596,405 in the previous year. Of this sum 32 per cent. was spent on water-supply, 1 per cent. on drainage, 12 per cent. on conservancy and 9 per cent. on other sanitary works. On rural sanitation £10,665 were spent during 1903, as compared with £11,563 during 1902.

At Rangoon the Hlawga water-supply scheme, estimated to cost £261,062, is approaching completion, and it is anticipated that it will be in working order in March 1905. The present water-supply has been augmented by sinking artesian wells.

The Mandalay water-supply project which contemplated the sinking of wells on the " Smreker " system and pumping the water to a reservoir located on Mandalay hill, whence it was to be delivered in pipes by gravitation, has been completed, but it is stated that the cost is beyond the means of the Mandalay tax-payers; and a proposal is now under consideration for supplying water by means of artesian wells.

The water-supply scheme proposed for Akyab has made no advance, but the Sanitary Engineer reports that the survey has been completed and that the project is under preparation.

At Prome the drainage scheme is being carried out piece-meal as funds become available, and during 1903 £910 were spent on this account, about half the town being now provided with good masonry drains. A sum of £6,564 was expended during the year on the new water-works of this town.

The water-supply scheme for Moulmein is progressing steadily and it is hoped that the work will be completed before March 1905.

A small septic tank installation has recently been constructed at Maymyo, and an interesting report by Mr. Gabbet, Executive Engineer, on the working of the installation has been commended to the attention of all municipal bodies in Burma.

Two meetings of the Sanitary Board were held during the year. At the first meeting held at Rangoon, the Board considered and disposed of references forwarded by civil officers and municipalities asking for advice on sanitary questions and projects. Type designs for markets, slaughter-houses, latrines, and incinerators were also considered. At the second meeting held at Moulmein, proposals for a surface drainage scheme and for an underground sewage system for Moulmein town were considered. The proposal for a surface drainage scheme was approved, and the consideration of proposals for sewers postponed pending completion of the surface drains.

General Remarks.

Red Sea Pilgrim Traffic.—For the pilgrim season of 1902-03 the Government of India announced that on their representation, His Majesty's Government had consented to remove the restrictions with regard to pilgrimage to the Hejaz which, in consequence of the continued prevalence of plague in India, had been in force during the past four seasons. In announcing the change of policy it was explained that the restrictions imposed on the liberty of His Majesty's Muhammadan subjects had at no time been agreeable to the Government of India, but had been rendered necessary in consequence of the apprehensions of certain European Powers that plague might be conveyed to Europe by Indian pilgrims. The previous orders were cancelled, and it was prescribed that no person should be permitted to embark with the object of making a pilgrimage to Mecca except at the ports of Bombay and Karachi in the Bombay Presidency, at Chittagong in the province of Bengal or at some one port in Madras which would be notified by the local Government of that Presidency. It was subsequently decided that a port should not be opened in Madras for the departure of pilgrims and that all Southern India pilgrims should be assembled in the Bombay Central Camp. All intending pilgrims were to be kept under observation until all risk of their carrying plague infection was over, and they were then to be conveyed from the place of observation to the port of embarkation. No passage tickets for the Hejaz were to be sold except at the places at which the pilgrims were detained under observation. Notwithstanding the removal of all restrictions as regards departure from India intending pilgrims were again advised, in view of the inconvenience likely to be experienced by them in Arabia, to defer their visit to another season.

According to the report on the Camaran Lazaret for the year 1902-03, twelve steamers conveying in all 5,125 pilgrims arrived from India. Four steamers sailed from Chittagong with 1,902 pilgrims, seven from Bombay with 3,042 pilgrims and one from Karachi with 181 pilgrims. All the vessels arrived at Camaran between the 24th of December, 1902, and the 18th of February, 1903.

The total number of deaths among Indian pilgrims at sea en route to Camaran was 15, the principal causes of death being malarial fevers, general debility and old age. During the period of detention at Camaran three deaths among British Indians are reported to have occurred, but no infectious disease made its appearance on the island.

Both before commencing the period of ten days' quarantine at Camaran and at the termination of that period the Indian pilgrims were this year required to undergo disinfection. The second disinfection is, in the British Vice-Consul's opinion, unnecessary and entails great hardship.

The Haj fell on the 9th of March, 1903; the weather was favourable and the general health good. Towards the end of April a few cases of small-pox occurred, but only one Indian pilgrim was attacked. Special sanitary measures appear to have been taken, and the sanitary condition of Mecca was greatly improved as compared with previous years.

All the pilgrims from India, irrespective of the port from which they had embarked, returned to Bombay. They were conveyed in 13 vessels which arrived between the 5th of April and the 20th of June, 1903. During the journey by sea nine deaths, one of which was due to small-pox, occurred. Four of the steamers arrived at Bombay with cases of small-pox (seven in all) on board. In accordance with the usual practice, pilgrims whose homes were up-country or beyond the frontier were not allowed to enter Bombay town but were despatched by rail direct from the landing sheds to their homes. The effects of all pilgrims were disinfected after disembarkation.

The improvidence of pilgrims from India is evidenced by the fact that in May between 200 and 300 were destitute, and a large number had no money to pay for their return journey to India. The British Vice-Consul at Jeddah induced the Bombay and Persia Steam Navigation Company to convey 356 destitute pilgrims to India without payment and 150 at Rs. 5 each, the Consulate providing food for the journey out of the Indian Pilgrim Relief Fund.

With regard to the payment of sanitary dues levied at Camaran, it may be noted that this season 30 per cent. of the Indian pilgrims paid their fees in gold and benefited accordingly.

Malaria.—In these reports for the years 1901 and 1902 summaries were given of the experiments in mosquito destruction carried on at Mian Mir by Captain James and Lieutenant Christophers. Since the full accounts of the work done by these officers were published the experiments have been the subject of many criticisms, some of them favourable and some of them unfavourable. Of the unfavourable criticisms some are just and will be useful in respect of the conduct of future experiments, but some can have been made only in forgetfulness of the state of knowledge when the experiments were initiated, and very many seem to be founded upon a misconception of their intention and scope. In the somewhat scanty accounts of other experiments of a similar nature, we find that anti-mosquito operations involving, at the most, inconsiderable engineering works were carried out with the immediate result of producing an astonishing diminution of the incidence of malarial fevers in the locality—as gauged by the entries in dispensary books; but in some cases it would appear that, before the anti-mosquito operations, malarial fevers were diagnosed from clinical symptoms, and, after the operations, by the use of the microscope. When a change of this sort is made in the method of diagnosis in India, equally astonishing results ensue, apart altogether from any anti-malarial measures.

At Mian Mir the main operations were directed against mosquitoes and an attempt was made to ascertain the degree to which their multiplication could be limited by such proceedings as are within the compass of a mosquito brigade. In the present state of our knowledge it must be obvious to any one that, if mosquitoes can be exterminated in an area, this is the best way to get rid of malaria; the use of mosquito curtains and quinine, however valuable in individual prophylaxis, being merely palliative in the case of a community. The experiments showed that in such a cantonment as Mian Mir mosquito destruction is beyond the powers of a mosquito brigade, and it becomes a problem what is the best method, or combination of methods, to suppress the disease in such a place. The first question is, what engineering works and what restriction of cultivation will bring mosquito destruction within the powers of a mosquito brigade; and the second, what will be the cost of the engineering works and of the restriction of cultivation in money and in the amenities of life. If the cost in either direction is excessive, it has to be decided whether it would not be well, in the first instance, to try the effect of removing bazaars and houses inhabited by native children to a distance from barracks, treating with quinine all native children found to be infected, preventing the breeding of mosquitoes within, say, two hundred yards from barracks, the issue of mosquito-curtains to the men, and the prophylactic use of quinine. If all those measures fail and the abandonment of the cantonment is out of the question, then we must fall back upon great drainage works and restrict cultivation to the limit which will render the extirpation of mosquitoes possible without rendering the cantonment uninhabitable by man. Where, on the other hand, ample funds and labour are available, and where it is considered that the probable reduction in the amount of malaria will sufficiently compensate for any disadvantages, economic or other, which can scarcely be avoided, it is doubtless preferable to commence forthwith extensive works of surface drainage and the filling up of all hollows and surface inequalities with the object of preventing the breeding of mosquitoes.

The question is finally one of cost and convenience, and where the local circumstances vary so greatly each problem must be judged on its merits, for the method which may succeed in one place may fail completely elsewhere.

In the case of Mian Mir the military authorities have decided to adopt the latter of the two courses mentioned above. In a special order lately issued by the General Officer Commanding the Lahore Division it is stated that in Mian Mir the following measures will be carried out:—(1) closing of canal irrigation; (2) levelling in of all hollows; (3) surface drainage; (4) removal of jungle grass and bush; (5) proper disposal of water used for washing or otherwise polluted; (6) proper disposal of refuse; (7) sanitation of cook-houses; (8) sanitation of servants' houses; (9) sanitation and reduction of extent of various bazaars. With reference to the first and second of these measures it has been decided that the filling in of canal cuts and the levelling of hollows made for building lines shall be carried out as a military fatigue duty. The results of this experiment will be watched with great interest.

When it was found that mosquito destruction by simple measures was impossible in Mian Mir, Captain James was placed on special duty to visit other malarious contonments with a view to further experiments. During 1904 the cantonments of Delhi Fort, Meerut, Allahabad Fort and Fatehgarh were examined by Captain James

with the following results. Delhi Fort was visited in April and again in August. In the former month larvæ of anopheles were found in many pools and reservoirs of water in the grounds of the fort, but no adult insects could be found in the barracks, and new infections had not commenced among the troops. In August the number of breeding places had increased very greatly. Building operations were going on in the fort grounds, and numerous pools of water, in all of which anopheles larvæ were abundantly present, had formed near the barracks. Larvæ were also found in the Selimgarh channel, which runs just outside the wall of the fort. Adult anopheles were very numerous in the barracks and the troops were beginning to suffer severely from malarial fever. Early in the month 53 per cent. of the native children under 10 years of age living in the fort were found to have malarial parasites in their blood. The breeding places in the grounds of the fort itself are so numerous that to deal with them effectively would be a task of some difficulty; but, even if they could be done away with, there would still remain on one side, within 50 yards, the dangerous Selimgarh channel, and, within 300 yards, the river; on another, in close proximity to the fort, the native town of Delhi; and on a third, at a distance of about 1,000 yards, the lines of the native infantry. In view of the proximity of these extensive sources of anopheles, Captain James considers that an attempt to rid the fort of malaria-carrying mosquitoes by efforts directed only against the breeding places in the grounds of the fort itself would not be successful, and that to deal with the sources outside the fort is impracticable. He believes that the troops in Delhi Fort would willingly use mosquito curtains if they were provided with them, and that this measure is the best practical means of combating malaria in this fort.

The cantonment of Meerut was visited at the end of August. Like Mian Mir it extends over a wide area, and experimental operations would be best confined to the lines of one regiment. The three British units are located at some distance from one another, and, as in Mian Mir, if operations were carried out in one series of lines, control observations could be made in the others. A preliminary malarial survey was made in the lines of the British cavalry. At first sight these lines would seem to be well adapted for anti-mosquito operations for there is no irrigation in their immediate vicinity and apparently they are well drained. There is, however, no lack of anopheles, and numerous breeding places containing larvæ were present in the lines at the time of examination, and many adult insects were found in the barracks and harness rooms. Two classes of breeding places in the lines would be very difficult to deal with, viz.: (1) eight very large ponds, and (2) a deep drainage channel called the Abu nullah which runs along one side of the lines between the barracks and the village occupied by the syces. Numerous anopheles larvæ were found in the running water of this nullah and it is probably the chief breeding place of the malaria-carrying species. There is another feature which would probably prevent anti-mosquito measures carried out in these lines from being successful. Although on three sides of the lines there are extensive spaces of waste land, the fourth is in direct communication, by means of numerous bungalows, with the large cavalry bazaar. To deal with all the breeding places in the compounds of these bungalows, in the bazaar, and to a sufficient distance beyond it, would be a very difficult task. At the time of examination 25 per cent. of the children in this bazaar were infected with malarial parasites, but it is possible that, as in Mian Mir, the endemic index would rise rapidly in October. In the syce lines only 15 per cent. of the young children were infected with malarial parasites at the end of August, and, while this cantonment is not so malarious as Mian Mir, the season during which new infections occur is even shorter than in that cantonment—at most lasting from the beginning of September until about the middle of November. The outlook for the success of anti-mosquito measures is certainly more hopeful in Meerut than in Mian Mir, but in view of the difficulties already mentioned, and the fact that protection from malarial infection would be required for about two and a half months of the year only, there is reason to suppose that the disease could be combated more easily and probably more successfully by other methods.

Allahabad Fort was visited in the beginning of September. It is well drained and throughout the area inside the walls only two collections of water could be found. Both were the result of leakage from standpipes, and both contained numerous anopheles larvæ. One of the large cemented reservoirs in the arsenal grounds also contained numerous larvæ, but these reservoirs, as well as all other breeding places inside the fort, could be easily dealt with. Outside the fort there is, on the one side, the River Jumna, and on the others a broad open plain through which the railway runs.

At the time of inspection the river was in flood and could not be examined for larvæ, but it is probable that at times when it is low, numerous breeding places would be formed along its banks. The ground on the other side of the fort is much broken and interspersed with numerous holes, small tanks and ditches. Most of these were full of water and contained numerous anopheles larvæ. It is doubtful whether any of the breeding places outside the fort could be effectually dealt with, but the main objection to the initiation of an experiment against mosquitoes in Allahabad Fort is the fact that it appears to be only very slightly, if at all, malarious. There is no source in the immediate neighbourhood from which anopheles could become infected. Only ten native children were living in the fort at the time of inspection; all were examined but not one had an enlarged spleen and malarial parasites were not found in the blood of any. The village of Kydgunj, situated about one mile from the fort, is the nearest inhabited area. Twenty-five native children in this village were examined, but malarial parasites were not found in the blood of any, and not one had an enlarged spleen. It must be assumed, therefore, that new infections with malarial parasites occurring among people resident in the fort are derived, through the agency of mosquitoes, from relapsing cases occurring among the troops. And this is very probable, for it frequently happens that the troops who garrison Allahabad Fort have previously been stationed in Delhi, and that a large proportion are more or less saturated with malaria on their arrival in Allahabad. In 1903, for example, out of 51 recorded admissions and re-admissions for malarial fevers, 24 were among men of the 75th Company, Royal Garrison Artillery, who had arrived from Delhi in November, 1902. In the medical officer's opinion most of the remaining cases would have been more correctly returned under the heading of "simple continued fever" than under that of "ague." Having regard to these facts and to the difficulties of dealing with the breeding places of mosquitoes outside the fort, Captain James is of opinion that malaria will be best combated in Allahabad Fort by the administration of quinine to all men who have come from malarious stations, and by the use of mosquito curtains in the hospital and barracks.

Fatehgarh was the last place examined during the year. This station also appeared to be only very slightly, if at all, malarious. In the bazaar which is situated in the centre of the lines, 30 native children under 10 years of age were examined, but not one of them had an enlarged spleen and in no case were malarial parasites found. Apart from this fact, however, the ground upon which the cantonment stands is so broken and so full of ditches and holes that a crusade against mosquitoes could not be undertaken except at great expense. A kutcha water channel of considerable width and depth, receiving tributaries from all parts of the cantonment area, runs through the lines to the Ganges River. To deal with it alone would be an engineering work of some magnitude, and so many other ditches and large holes exist in the area that experimental anti-mosquito measures would be useless. A large number of the admissions for malarial fevers recorded in this station are undoubtedly relapses of infections contracted elsewhere, the unusually hard work necessitated during the training in the mounted infantry classes being a powerful contributing factor. The composition of the force in this cantonment is, moreover, such as to prevent a comparison of the statistics of sickness during one year with those of another being of value, for it is made up of detachments from three regiments stationed in different parts of India, and each detachment remains only three months.

An important parasite recently discovered in man.—A special feature of research during the present year has been the elucidation of facts regarding a hitherto entirely unknown parasite of man and the differentiation of the morbid conditions to which it gives rise. In last year's report brief reference was made to this important parasite, and the résumé of our knowledge on the subject given in that report may conveniently be amplified and brought up to date here.

The first reference in literature, which can be said to relate to this parasite, is contained in an article written in 1885 by Cunningham, who, in describing the pathological appearances of sections made from the tissues of a "Delhi boil," drew attention to the presence in the tissues of certain cells containing darkly staining bodies. At that time neither the examination of smears made from fresh tissues nor Romanowski's stain were in use, and therefore it is not surprising that Cunningham did not observe in the bodies the characteristic structure which has since been revealed by modern methods of chromatin staining. In 1891, Firth showed that the parasitic nature of the cells discovered by Cunningham was fully recognised by

naming them "sporozoa furunculosa," but from the date of his paper until 1903 no further mention of the parasite occurred. In February of that year Marchand described, before the Medical Society of Leipsic, certain curious ring-like bodies included in large cells in the bone marrow from a case of Banti's disease, but whilst hinting at the possibly parasitic nature of the bodies, he came to the conclusion that they were, in reality, the products of nuclear changes. In May, 1903, Leishman described certain bodies, each possessing two very characteristic chromatin masses, found by him in 1900 in smears from the spleen of a case of Dum Dum fever. He believed them to be parasitic in nature, and, studying material taken postmortem, often some time after death, and chiefly concerned with the appearance of the chromatin masses, he came to the conclusion that the bodies were trypanosomes which had become altered by the death of the host or by the action of cells during life. This view of the nature of the bodies was dispelled by Donovan, who, using material taken by spleen puncture during life, was the first to suspect that the bodies were a form of parasite as yet undescribed. Donovan forwarded specimens to both Ross and Laveran, and it was chiefly from the descriptions published by these two observers that the scientific world first realized the high interest and great importance of the discovery. Laveran and Mesnil boldly announced that the bodies were a hitherto undiscovered human parasite and gave a description of the appearances seen in films of splenic blood to which no material addition has since been made. They found forms included in a substance which they took to be the body of a red blood corpuscle altered by the presence of the parasite, as well as forms which were distinctly pear-shaped, and forms divided into two or more by a process of fission, and they finally came to the conclusion that the parasite was a new species of *Piroplasma*. Ross also published, in two notes, an accurate description of the appearances of blood drawn from the spleen. He drew attention especially to the substance in which the bodies were embedded, and, discarding the view that it was the altered substance of a red cell, he termed it merely a matrix, but stated his opinion that it was, in all probability, an integral part of the parasite, possibly fragments of a parent mass. For some time interest chiefly centred in the nature of this matrix, and in addition to the two views given above, Manson and Low gave it as their opinion that this substance was, in some cases at least, a secretion thrown out by the bodies themselves. The most probable hypothesis was that, finally given by Christophers, who, comparing the appearances seen in films of splenic blood with those in sections of the viscera, came to the conclusion that the matrix was merely the fragmented cytoplasm of the splenic cells in which the great majority of the parasites are, under natural circumstances, included. Whilst discussion was rife as to the nature of the parasite important facts were coming to light in regard to the clinical and pathological conditions to which it gave rise. For many years it had been recognised that in some cases of so-called "chronic malarial cachexia" a disease existed which by no means conformed to the ordinary type of malarial infection, and in which several observers had consistently failed to demonstrate malarial parasites in the peripheral blood. It was also extremely resistant to treatment, and was largely responsible for the high death-rate ascribed to malaria in India. This disease indeed was so prevalent as to give to the fever cases in the hospitals of Calcutta and Madras a distinctive character, which was very puzzling so long as it was thought to be a manifestation of malaria. It was not long after the discovery of the bodies before it was generally recognised that these anomalous cases of fever were those of infection by the new parasite and had no relation to malaria. Cases of the disease were also reported from China, Egypt, Arabia, South Africa and elsewhere, and it became evident that the parasite was the cause of one of the commonest, most widespread and important of tropical affections. A new point of interest arose in connection with *kala azar*. In December, 1903, Donovan stated his belief that the disease seen by him in Madras was identical with *kala azar*, a surmise strengthened by the examination of material sent to him by Bentley and afterwards fully confirmed by Rogers, who left no doubt that *kala azar*, Dum Dum fever and some cases of so-called malarial cachexia were one and the same disease.* Throughout all these researches the attention of workers had been entirely directed towards the relation of the parasite to the blood and to its presence

* As was to be expected there has been a tendency of late to regard *all* cases formerly diagnosed in India as "malarial cachexia with enlargement of the spleen" as being due to the newly discovered parasite. The recent work carried out in the Punjab by Captain James shows that this is not the case, and that true malaria cachexia must still be regarded as a disease of great importance in India.

in the liver and spleen. An entirely new aspect was therefore opened up when Wright discovered bodies very similar to those present in certain cases of enlarged spleen, in the tissues of an Oriental or Delhi Sore, and James, comparing the parasites obtained from cases of splenic enlargement with those from Oriental Sores, left no doubt that in appearance, at any rate, they were identical.

Wright defined Oriental Sore, as Cunningham and others before him had done, as a focal granuloma of the skin, and he described and figured as the essential condition, a large mass of granulation tissue composed of cells which were, for the most part, crowded with the protozoan bodies and were strongly reminiscent of the lepra cells in a leprosy tubercle. His work clearly demonstrated that in Oriental Sore the organism is present in a rôle entirely different to that of a blood parasite.

The significance of Wright's discovery was not at first clear, and the association of two such dissimilar diseases as splenomegaly and tropical ulcer gave rise to considerable bewilderment. The relationship of the two conditions became clearer as research proceeded. In some cases of splenomegaly the bodies were found by Donovan in small ulcers about the knees and elbows, whilst Christophers demonstrated their presence in the granulation tissue of intestinal ulcers and showed not only that the bodies occurred in the spleen, liver and bone-marrow, in ulcers and granulation tissue of the intestine, in papules and ulcers of the skin, in the testis, lungs, kidneys and lymphatic glands of the groin, but also that they were, in practically every case, included in the cytoplasm of cells, a fact later confirmed by Manson and Low who also independently found the bodies in lymphatic glands of the mesentery. In addition Christophers pointed out that the cells which the bodies occupied were chiefly endothelial cells of the capillaries and minute vessels of the viscera and granulation tissue, thus demonstrating a type of endothelial invasion. Whilst the infective processes and relations of the parasite to the tissues of the host were thus being gradually shown to involve much wider principles than had hitherto been suspected, interesting developments were taking place in regard to its zoological characters. In spite of the evidence against the trypansome nature of the bodies, the startling resemblance of the double chromatin masses to the centrosome and nucleus of the *Trypanosomata* has kept research continuously applied to the question of their relationship to this still far from worked out group. The publication by Schaudinn of a paper of almost revolutionary character still further concentrated attention upon this point. Among many items of protozoan development, Schaudinn described that of a halteridium of the stone-owl in the alimentary canal of a "culex" mosquito, and influenced by analogy, it was suggested by several observers that the newly discovered parasite probably went through a trypanosome stage. This suggestion has possibly received confirmation in some recent work by Rogers, who reports that by keeping blood containing the parasites for two or three days in a solution of citrate of sodium at a temperature of 22° C., he has succeeded in observing the development of the parasites into trypanosome-like forms.

Thus our knowledge of this parasite, gained in a period of about two years, has left its zoological position almost as uncertain as when it was first discovered. Whether the parasite has a real relation to the pathogenic trypanosomata of mammals or whether it merely passes through a flagellate stage, we cannot yet assert. The fact that Laveran still believes that the organism is a *Piroplasma* shows how inconclusive is the evidence for its inclusion in any of the orders or even classes of the Protozoa at present recognized.

As regards the infective process in man our knowledge had advanced considerably. The establishment of the fact of a granulomatous lesion and of an infective endothelial invasion by a protozoan is important, and the fact that probably the same protozoan is concerned, leads one to suspect that, just as there may be an invasion of the lung, of the skin, of the lymphatics, or even of the bloodstream, by a bacillus, so there may be by certain protozoans. The study of the disease in man has also brought into prominence the necessity for the examination of other tissues than the blood, especially of the great store viscera of the body and the lymphatic glands. It has also given some very suggestive clues in the study of splenic anæmias, and it has greatly simplified many problems in connection with malaria.

Of the method by which the disease is conveyed we know nothing, and the generally supposed absence of the parasite in the peripheral blood has led Manson and Low to suggest the fæces as a possible means of exit from the body. In this connection the observation of Christophers that the bodies are often present in the leucocytes of the peripheral blood, especially in advanced cases, is important and

the possibility of a blood-sucking carrier should not be lost sight of. Observations upon the conditions under which the disease is contracted are much needed in order to give some more certain foundation for experimental research in this very important matter.*

Further researches upon this parasite.—Since the above was written, a report has been received from Lieutenant S. R. Christophers, I.M.S., containing an account of some researches carried out by him in connection with the development undergone by the parasites when kept at a low temperature in a solution of citrate of sodium. It will be remembered that, at the recent meeting of the British Medical Association, Captain Leonard Rogers, I.M.S., announced that by adding blood obtained by splenic puncture from cases of enlarged spleen caused by the parasites to a small quantity of sterile citrate of sodium solution, and keeping it at a temperature of 22° C. for two or three days, he had succeeded in observing the development of the parasites into trypanosomes. He found that when the citrated splenic blood was kept at blood heat the parasites very quickly disappeared, but that when kept in a cold incubator at 27° C. they retained their usual shape and characters for several days. Moreover, they increased markedly in numbers, and very numerous dividing forms were present. At a temperature of 27° C., however, the parasites lived for only three or four days, and he therefore reduced the temperature of the incubator to 22° C. This temperature was found to be most suitable for the development of the parasites, and he reported that in the cultures obtained from two cases "unmistakeable trypanosoma" appeared, together with smaller pear-shaped flagellated bodies and other intermediate forms. "The most marked of the cases showed completely developed trypanosoma with thick flagella macro-nucleus, and micro-nucleus, after incubation for one day, while the living forms were also seen in the blood culture, moving rapidly among the corpuscles." . . . "The other case in which the trypanosoma have developed was a case of *kala azar* from Assam, and after incubating for five days at 22° C. we found in the citrated blood a number of intermediate forms and a few fully-developed trypanosoma."†

While there could be no doubt that Captain Rogers had made a most important discovery regarding the development of the parasites outside the human body, it was apparent from an examination of the illustrations attached to his article that the bodies which he regarded as fully-developed trypanosomes differed considerably from ordinary trypanosomes met with in animals. They possessed no undulating membrane, the micro-nucleus or centrosome was situated at the end of the parasite from which the flagellum emerged instead of at the opposite end as in ordinary trypanosomes, and the flagellum appeared to pass out of the parasite directly from the micro-nucleus instead of being continued along the whole length of the body of the parasite.

† British Medical Journal, 17th September, 1904, page 648.

Lieutenant Christophers reports that, influenced by the discovery of Captain Rogers, he has kept blood obtained by splenic puncture from suitable cases under the necessary conditions, and has succeeded in observing a development of the parasites resulting in a great increase in numbers and the formation of flagellate forms. The following is a brief summary of the results obtained by Lieutenant Christophers in one of his cases. About 1 c.c. of blood was removed from the spleen of a case having a greatly enlarged spleen and a high, but irregular temperature. Parasites were fairly numerous in a film made at the time of puncture. The blood was kept in a very small quantity of citrate of sodium solution at a temperature varying between 22° C. and 24° C. On the third day a number of the bodies were unchanged in appearance, but a very few were seen in which the protoplasm was increased in amount and was stained a dark blue. On the fourth day the large forms with darkly staining protoplasm were very conspicuous. As a rule they were circular in shape and the two chromatin masses were not so markedly at the periphery as in parasites seen in blood taken directly from the spleen. On the fifth day still larger forms were seen. The majority were as large or larger than a red blood corpuscle, measuring as much as eight micromillimetres in diameter. Their protoplasm was granular and stained distinctly blue. The large chromatin mass had increased in size and its substance was arranged in the form of numerous granules. The small chromatin mass, though slightly enlarged, retained its original shape and appearance. Many of the large forms were seen in various stages of fission and groups of two and of four forms were more numerous than single bodies. In addition, considerably elongated parasites, having the small chromatin mass or centrosome at one end, were present. In some of the forms a new structure, consisting of a circular vacuolic pink-staining area, was apparent, and by careful focussing an appearance resembling a coiled thread could sometimes be made out. The contents of some of the vacuolic areas appeared to have been extruded from the parasites and masses of pink staining material showing the same shade of colour were frequently seen lying outside the body of the parasite near the extremity occupied by the centrosome. In a few cases delicate faintly stained irregular flagella-like filaments were seen to be continuous with partially extruded pink substance. On the sixth day the bodies were almost invariably in groups of from four to ten, the individual bodies being rarely of less size than a red blood cell. Pear-shaped forms were the most frequent, the large end containing the nucleus, while the thin end contained the centrosome. The thin ends of the pear-shaped bodies invariably lay close together attached to an indistinctly stained irregular mass forming the centre of the group. The thick ends projected in a characteristic way. Many of the bodies possessed a short, thick, clearly outlined, flagellum, the terminal extremity of which was distinctly thickened or clubbed. In many instances the flagellum could be clearly seen entering the body of the parasite. In some cases it appeared to arise directly from the centrosome, but in most a short gap intervened. Its length was in some cases at least fifteen micromillimetres. A certain number of forms were more elongated, but though they were of considerable length and tenuity no tendency of the flagellum to pass backwards towards the nucleus was observed. In a number of instances the bodies appeared to have developed and subdivided while still included in the cytoplasm of a cell. On the seventh day groups of many forms were most commonly encountered, several bodies in each group showing long flagella. Fission appeared to be in active progress and the central gelatinous-like mass was very voluminous. On the ninth day single forms were rare and closely aggregated masses of the bodies were almost exclusively seen. On the twelfth day subdivision had progressed still further. Individual forms were often diminished in size and it was often difficult to trace their outlines and to assign the chromatin masses to their respective parasites. The formation of flagella was a constant feature though it occurred in only a limited number of parasites in each group. No sign of degenerative changes or of a diminution in the number of groups had occurred and fission in an irregular way was still in active progress. Throughout the examinations no forms resembling adult trypanosomes were seen and the flagellum in every case, even in the very elongated forms, passed directly outwards from the centrosome.

Lieutenant Christophers considers that the most advanced forms seen by him are not essentially different from the most advanced forms seen by Captain Rogers, but he does not feel justified in stating that they are fully developed trypanosomes. He remarks that although in his own specimens and in the drawings illustrating Captain Rogers' article there are forms resembling some developmental forms of trypanosomata, the relation of the flagellum to the nucleus even in the most advanced

form is certainly not that found in a fully-developed trypanosome. Although it is possible that the parasites must be included among the class of *Flagellata*, the improbability that they belong to the genus *Trypanosoma* is the greater when we consider that the conditions present in infections by the parasite under discussion are entirely different from those of ordinary mammalian or human trypanosome infection, and for these reasons it would be rash to form an opinion as to the exact zoological position of the parasites until further work has been done.

Oriental or Delhi Sore.—It is satisfactory to note that the etiology of yet another important disease in India has been to a great extent cleared up as a result of recent researches. In view of the discovery in America of certain protozoal organisms in the tissues of a "tropical ulcer" or "Delhi Sore," Captain James, I.M.S., was directed in April, 1904, to proceed to Delhi for the purpose of investigating the etiology of "Delhi Sore." He found that in Delhi itself the disease was somewhat rare, but with the assistance of Civil Surgeons in other parts of India he succeeded in obtaining specimens from 13 sores diagnosed either as "Oriental Sore," "Delhi Sore," "Lahore Sore" or "Sind Sore." In the case of three of these sores the correctness of the diagnosis was doubtful, and in specimens from them nothing of importance was found. In specimens from nine of the remaining ten sores were found numerous parasites similar to those recently described by Wright as being present in a case occurring in America. The remaining case was a typical "Delhi Sore," but at the time of examination it had already lasted eighteen months and was healing up. There can be no doubt that true "Oriental Sores" occurring in India are caused by the parasites found by Captain James in so large a proportion of his cases, and the fact that the parasites were found in sores occurring in places so far distant from one another as Delhi, Karnal, Shahabad, Lahore and Quetta, indicates not only the wide distribution of the parasites, but also the identity of the disease known in India under so many names.* The Indian disease is no doubt identical also with the "Aleppo Boil" and "Baghdad Sore," &c., of other countries, for in addition to the case reported in America by Wright, Drs. Martzinowsky and Bogroff have recorded the finding of similar parasites in a case diagnosed as "Aleppo Boil" in Moscow. Captain James has compared the parasites obtained from cases of "Oriental Sore" occurring in the Punjab with those obtained by puncture of the spleen from cases of *kala azar* in Assam, and he considers that under the microscope the former parasites cannot be distinguished from the latter. On the other hand, he has carried out an investigation which goes far to prove that the parasite as met with in the Punjab, causes only the comparatively mild local skin affection known as "Delhi Sore," while as met with in Assam it causes only the dangerous general disease called *kala azar*. If this result is confirmed it will open up many interesting points for further investigation, some of which are the following: (1) the parasites of "Delhi Sore" and of *kala azar*, though very similar in appearance may in reality belong to different species, each producing a different pathological effect; (2) assuming that the parasites of "Delhi Sore" and of *kala azar* are identical, how is the fact to be explained that in one part of India they produce only a local skin infection while in another they produce only a general disease? (3) The point of infection in "Delhi Sore" is obviously the skin; if the parasites of this disease and of *kala azar* are identical the point of infection in the latter disease cannot be the skin, for even when numerous parasites are present in a "Delhi Sore" for months, no general disease like *kala azar* results, and the latter disease does not exist in some places where local skin infections with the parasites are not uncommon. (4) It follows that if any biting insect were shown to be the infecting agent of "Delhi Sores" it would not necessarily prove that *kala azar* is contracted by the same agency.

The investigation of Cancer.—In October, 1901, a scheme was initiated in England having for its object the investigation of the cause, nature, and treatment of cancer. For this purpose a fund—now called the Imperial Cancer Research Fund—was started, and in July, 1902, the investigation was set going, under the patronage of His Majesty the King, by the Royal College of Physicians of London and the Royal College of Surgeons of England. In the following year the Government of India were invited to co-operate in the investigation on lines similar to those which

* Since this paragraph was written, Captain James has found the parasite in films from four Frontier Sores" occurring in Dera Ismail Khan.

had been commended to the attention of the colonies. It had been pointed out by the Executive Committee of the Fund that in investigating cancer one of the chief matters of importance is to endeavour to ascertain whether the incidence of the disease is restricted to any race, or is dependent upon the circumstances of climate, soil, &c., and attention had been especially directed to the necessity for seeking whatever evidence there may be in India of the occurrence or non-occurrence of malignant new growths among natives. The Government of India accordingly caused a memorandum to be drawn up indicating the method and extent to which they considered assistance on these lines might be rendered to the Executive Committee of the Fund, and medical officers in charge of Government and other hospitals in India were asked to record their observations upon cases of cancer admitted to their hospitals in a form attached to the memorandum. The form provides for a complete description of each case and for all matters likely to throw light on the causation of the disease, and is prepared by the recording medical officer in duplicate, the original being sent to the Administrative Medical Officer of the Province and the duplicate direct to the Superintendent of Cancer Research, Victoria Embankment, London. The original reports received by Administrative Medical Officers are forwarded by them at the end of each year to the Statistical Officer of the Government of India in the Sanitary and Medical Departments. Writing in July, 1904, the Superintendent of the Fund stated that a considerable number of reports on cases of cancer had reached him from medical officers in India. He pointed out that while the majority of the reports were quite satisfactory, in a few cases the ages of patients had been omitted. Measures were taken to prevent this omission in future returns and the information supplied from India is now as complete as is possible.

Pasteur Institute of India.—The work of the Pasteur Institute, Kasauli, has increased enormously, but as the annual report of the Institute for the year ending August 8th, 1904, has not yet been published it cannot be noticed here.

The scheme for a Pasteur Institute for Southern India, for which a site has been selected at Coonoor in the Nilgiri Hills, is progressing.

Scientific memoirs.—Since the issue of last report the following memoirs have been published. No. 8.—A preliminary report on a Parasite found in persons suffering from enlargement of the spleen in India—By Lieutenant S. R. Christophers, I.M.S. No. 9.—Second report of the Anti-malarial operations at Mian Mir, 1901-1903—By Lieutenant S. R. Christophers, I.M.S. No. 10.—Specificity of Anti-venomous Sera (second communication)—By Captain G. Lamb, I.M.S. No. 11.—On a Parasite found in persons suffering from enlargement of the spleen in India—second report—By Lieutenant S. R. Christophers, I.M.S. No. 12.—On the morphology, teratology and diclinism of the flowers of Cannabis—By Major D. Prain, I.M.S.

Reorganisation of the Sanitary Department.—For some time past the problem of the reorganisation of the Sanitary Department has received the anxious attention of the Government of India. It was felt that while considerable changes were necessary to adapt the administration of the department to the requirements of modern knowledge, it was no longer possible that this administration should form only a part of the work of the officer selected to fill the office of Director-General of the Indian Medical Service.

The Government of India in their Home Department Resolution, No. 1273-1290 (Sanitary), of the 8th September, 1904, after sketching briefly the history of Sanitary Administration in India and discussing proposals recently laid before them for its improvement, give their reasons for determining that the first step to be taken in any scheme of re-organisation is the appointment of a separate Sanitary Commissioner with the Government of India. They define the duties of the Sanitary Commissioner in paragraph 10 of this resolution.

> His advice will be of value not only in settling in consultation with the local Governments and Administrations the principles on which an advance should be made, but also in giving effect to those principles, with due regard to local conditions and popular prepossessions, to the extent of the resources that are available from time to time. But the Sanitary Commissioner's work will also have another and an equally important side, the organization and direction of research throughout India, which will steadily increase with the progress of the scheme already sanctioned for the establishment on lines similar

to those recommended by the Plague Commission of fully equipped institutes for the study of health problems in India. This scheme provides for a central laboratory devoted mainly to original research of a general character, and the manufacture of antivenene and certain curative sera. In each of the larger provinces there will be a provincial laboratory, the primary functions of which will be to conduct diagnosis and special research connected with local conditions. One of these, the laboratory at Parel, will also carry on the manufacture of plague prophylactic. If the scheme is to be efficiently worked and to produce results which will justify the expenditure incurred upon it, the whole body of institutions which it comprises must be under the control of a competent sanitary expert who can supervise, organize and co-ordinate the work, can prevent conflict and overlapping, and being himself in charge of sanitary affairs throughout India, can determine what questions call for scientific investigation and where and by whom the work should be done.

They define his position in paragraph 12.

In dealing with technical sanitary questions the Sanitary Commissioner must obviously have a free hand. As regards administrative questions the Government of India have considered, but have decided to abandon, the idea of making him subordinate to the Director-General, Indian Medical Service. Efficiency and despatch of business will be the better secured if the Sanitary Commissioner has an independent position; while the co-operation and co-ordination which must be maintained between the two offices can be ensured without formally subordinating one to the other. It remains to define the relations of the new appointment to the provincial Governments. The Government of India have no intention of relieving local Governments of the direct control and responsibility which they have hitherto exercised in sanitary matters, or of weakening their authority over provincial sanitary establishments. The views held by the civil members of the Plague Commission upon this point are entirely endorsed both by the Government of India and His Majesty's Government. The main functions of the Sanitary Commissioner will as heretofore be to advise the Government of India upon sanitary and bacteriological questions. He will not be permitted to encroach in any respect upon the authority of local Governments over the officers under their control. But he will be empowered to consult and confer with them informally upon matters connected with sanitation and will in this respect occupy a position closely analogous to that of the Director-General of Education. He should also correspond unofficially with the provincial Sanitary Commissioners and the heads of provincial laboratories upon points of departmental procedure, form and statistics, and purely technical questions.

The Sanitary Commissioner with the Government of India entered on the duties of the new appointment on the 6th September, 1904.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR MADRAS FOR 1903.

(*Lieutenant-Colonel W. G. King, C.I.E., I.M.S.*)

General Population.*

In the presence of a prosperous season, it is probable that emigration has been less active than in the previous quinquennium, when high prices prevailed; but data are not available, as the usual returns by the Revenue Board have not yet been issued by it. The natural increase of the population according to registration was 768,735. The number for which registration returns were received during the year was 37,315,611, leaving 897,101† of the total census population unaccounted for. As usual, there has been no want of effort on the part of Government and the officers concerned to bring about improvements of methods of registration, and the whole subject was again considered by Government during the year (G.O., No. 329, Rev., dated 25th March, 1903). There are, however, two very evident flaws in registration in rural areas that cannot be ignored; one is the fact that control of Revenue authorities of zamindari villages is imperfect, and consequently as a rule the total average results in certain districts have been hitherto seriously reduced by errors owing to the omission of events. The statistics for 1903, however, show great improvement in this particular. The second is the impossibility of trusting registration to the existing agency, when a population assumes certain proportions. I have long held that the moment a town possesses 5,000 inhabitants, it is beyond the powers of the village revenue officials to keep a strict record of vital statistics. If this statement be true of villages containing a population of 5,000, still more is it correct of those of 10,000 and over, and I believe, whether compulsory registration be put in force or not, unless a special staff be employed such as might economically result by a combination of sanitary, vaccination, and registration duties under one department, that registration must still remain defective. Consequently, it has seemed to me necessary to secure that registration returns of towns should be so compiled as to exhibit separately towns having populations of above 5,000 and above 10,000, and showing where the registration is compulsory and where not; so as to be able to point out to the local authorities concerned where the flaws actually exist, notwithstanding the theoretical enforcement of compulsion. With the consent of the Revenue Board (Proceedings No. 177, dated 23rd May, 1903), the statements of vital statistics are now procurable compiled in this manner. The ruling had been in force for six months during 1903. The statistics obtained show that my contention as to the size of towns affecting results is sound. Notwithstanding compulsion in both instances, the total average for towns containing over 5,000 and below 10,000 inhabitants amounts to 28·1 for births and 21·1 for deaths; whereas in towns of 10,000 and over, the total average rate for births is 25·2 and deaths 19·8. In some of the towns containing 10,000 inhabitants, under compulsory registration, somewhat startling results are obtained; thus, in Yemmiganúru, in the Bellary district, the birth-rate is said to be 9·8 and death-rate 15·8; for Gopichettipoliem in Coimbatore district, the birth-rate returned is 7·8 and the death-rate 4·3; in Gudur in Nellore district, the birth-rate is declared to be 11·5 and death-rate 10·2; whilst Nellikuppam in South Arcot district, not to be outdone by its northern compeers, is content with a birth-rate of 3 and a death-rate of 2·9. The attention of the authorities concerned has been drawn to these results, and, as they are unusually bad, I had no struggle with my conscience in

---

* Throughout the Report rates per 1,000 only are quoted, unless it be specifically stated otherwise; consequently, the constant repetition of the words "per 1,000" is not thought necessary.

† This figure represents the combined populations of (1) the Agency tracts of Vizagapatam (850,960); Banganapalle State (32,259); Amindivi islands (3,608); and the Laccadives (10,274).

doing so; but, it seems to me a hopeless task for them to exhibit anything approaching correct birth and death-rates in towns possessed of populations of 10,000 or over, if the efforts of the Village Heads alone are to be relied upon. In Ganjám, statistical results are uniformly untrustworthy, owing to the apparent impossibility of the local authorities securing returns from the same number of villages monthly. In G.O., No. 628 L., dated 4th July, 1902, Government directed Collectors to select certain localities in their districts and to cause registration to be so effectually supervised that the cause of former inefficiency should be ascertained. Up to date, I am in possession of reports from only four Collectors on this subject. Beyond giving reason for a few cases escaping detection, no new fact of importance is revealed, except that in one union, where compulsory registration was in force, there had been neglect to require attendance of the Registrar at definite hours.

To all Municipal Registrars has been sent a pamphlet written by my late Personal Assistant, Assistant Surgeon Kistnamurthi, in which all common diseases are described in simple language. This, in addition to the course of instruction to Municipal Registrars by District Medical and Sanitary Officers previously arranged for, should go towards improving accuracy of registration of death causation.

In municipal areas, disobedience to compulsory clauses of the Act was followed by prosecution in 1,264 cases.

Births in Districts.—The total number of registered births being 1,165,080, the birth-rate of the Presidency during 1903, when reckoned upon the census population, is 31·2, against the average of the preceding 10 years ending 1900 of 28·5, of 25·1 for 1901, and 28·2 for 1902. A certain amount of this increase is discounted by the fact that, when reckoned upon the estimated population, the birth-rate is 30·6. Nevertheless, there is room to think that some improvement has occurred in registration, and no room to doubt that removal of the depressing influence on fecundity of high prices of food has been recovered from, as an effect of the prosperous seasons of 1902 and 1903. In my report of 1901, I pointed out that the districts of Chingleput, North Arcot, Madras, Kistna, and Kurnool suffered special diminution of their birth-rates, in all probability in response to this influence; and I suggested, in my Report of 1902, it would be of some interest to ascertain whether these districts, which showed decreased birth-rates out of proportion to those of other districts which had been less affected, would exhibit a reaction at a greater rate than these, as soon as the results of better food supplies had time to operate. Taking Chingleput, it is found that, in 1901, the birth-rate was 26·6; this has increased to 39·2, thus exceeding the total average by 3·6. Kistna has from a rate of 27·2 advanced to 33·5. Kurnool from 23·3 has advanced to 31·3, thus exceeding its total average of 30·2. Madras has advanced from 37·1 to 39, but it has not yet reached the total average of 40·9. Here, as already noted, prices have not fallen to the same extent as elsewhere. North Arcot from 19·1 in 1901 has advanced to 29·1, and, therefore, has exceeded the total average by 1·4. On the other hand, the birth-rate of the year has exceeded the total average in 15 of the remaining 17 districts, which were also subjected to the strain of high prices, but in a less marked degree. Of these, Nellore and Malabar should have also been selected by me. There is, therefore, sufficient reason to regard the rate of recovery in the affected districts since 1901, with the exception of Madras, as proportionately greater than during the period when prices were continuously nearer normal. Such facts as these go to disprove the popular opinion that high prices of food and epidemics specially affecting infantile life, cause decrease in the population, or, put in another way, that scarcity of food is a divine dispensation in respect to increase of population; there are physiological reasons why this opinion would be true only if the causes were permanently in operation.

Deaths in Districts.—Notwithstanding the increased birth-rate and its frequent sequel of increasing the total mortality by increased infantile deaths, the total death-rate of the Presidency was but 22·2 against the total average of 21·4, and, when reckoned upon the estimated population, 21·7. No notable increase of mortality has occurred except in Anantapur, Coimbatore, Salem, South Canara and Malabar. In the case of the first four districts, the increase is due to plague. In Malabar, irrespective of improved registration (which is evident from the simultaneous better birth-rate registered side by side with the increased mortality), the

increase seems to have been chiefly due to cholera. Exclusive of cholera, small-pox and plague, the total mortality of the Presidency was 770,964, affording a rate of 20·7.

Reckoned upon registered births, the total deaths of infants below one year of age was 177·6 against 168 of the preceding year—an increase largely due to mortality of infants in plague-infected areas. In both years, the ratio of deaths was practically the same, namely, 100 males to 90·1 females in the year 1903 against 100 males to 90·2 females in the year 1902. In 12 districts the average of 9·9 per cent. difference between male and female deaths was exceeded. The highest rate registered was in Madras and Chingleput districts, where it amounted to 286·1 and 210·6, respectively. It is probable that the marked endemic prevalence of diarrhœa and dysentery in these districts had much to do with this result.

Births in Municipalities.—85,824 births were registered in municipalities in a census population of 2,406,455, representing a birth-rate of 35·7. On the estimated population, the birth-rate would be 34·6. The ratio of male to female births was 100 to 94·3. This may be contrasted with the ratio for England and Wales from 1896 to 1900, which was 100 males to 96·6 females. When compared with last year, Coimbatore, Ootacamund, Tiruppattúr and Vellore, exhibit slight decreases in their respective rates which may be accounted for by exodus of the people during plague, and by less efficient registration of births during stress of preventive work. But, on the other hand, Adóni and Bellary, which were similarly affected, show no such decrease. Cocanada, Masulipatam, Periyakulam, Kodaikánal, Tirupati, Vániyambádi, Tinnevelly and Srívilliputtúr show a falling off in results, which may fairly be ascribed to careless registration. With the exception of the towns named, an increase of the birth-rate has occurred in all municipalities; a result which may be ascribed, in part, to improved registration, and, in part, to relief from the conditions incident to dear food which have already been referred to. The highest registered birth-rate of 50·2 is reported by Vániyambádi against that for the preceding year of 63·1. This falling off of the normally high birth-rate of this town, notwithstanding the continued presence of a large section of Muhammadans who are well off and possessed of zenanas, is probably due to the fact that the population has suffered heavily from plague, and that some amount of emigration has occurred. Of municipal towns not possessed of this abnormal character of the population, Karúr has shown the highest birth-rate, namely, 45·3.

Deaths in Municipalities.—The total mortality rate for municipal towns for the year, namely, 32·7, shows but little change when compared with that for the preceding year, namely, 32·5. The chief change in causation of mortality was a slight decrease in the case of cholera and small-pox, and a slight increase in the mortality from plague. In the municipal towns of Coimbatore, Ootacamund, Coonoor, Vellore, Vániyambádi and Tiruppattúr, the increased mortality was due to plague. In Chicacole, Berhampur, Palni, Calicut, Gudiyáttam, Dindigul, Cuddapah, Parlákimedi, Karúr, Cochin, Trichinopoly, Mánnárgudi, Vizagapatam and Tiruvannámalai, the apparent increase is due to increased activity in registration, as the birth-rate has synchronously increased. In Tellicherry increased mortality is exhibited under "dysentery and diarrhœa," "respiratory diseases" and "fevers." Such a combination would give rise to suspicion of the existence of unrecognised plague. The Civil Surgeon informs me that he has no reason to suspect that this has been the case. In Salem, there has been a remarkable increase in the efficiency of registration, as the birth-rate has advanced from 37·1 in 1902 to 43; the heavy death-rate obtained is largely due to this cause, as, if deaths from cholera, &c., be subtracted, the more reasonable mortality, having regard to the birth-rate, of 34·0 per 1,000 is arrived at. It is probable, however, the full birth-rate has not yet been secured in this municipality, but I think it very unlikely that cases of death escape notice, as the town has throughout the year been under the system of observation for plague, and, by personal inspection, I have ascertained that the duty of checking mortality is very carefully carried out. The severe rate of 162·4 in the case of Vániyambádi is in part accounted for by the heavy incidence of plague in the town, owing to the inhabitants obstinately refusing the precaution of evacuation. This was also added to by a number of deaths during floods, which swamped a portion of the town in November, 1903.

In 1902, the total average infantile death-rate in municipalities reckoned upon the registered births per 1,000 amounted to 233·3, and, in my report for that year,

I pointed out that the decline of 4 per 1,000 compared with 1901 recorded for that period probably represented the withdrawal of the influence of high price of grain upon the adult, and its indirect influence upon infantile life. This remark is justified by the practically unaltered figure for 1903, which is 234 against 233·3 for 1902. The proportion of male to female deaths among infants below one year of age was 100 to 88·5 against 90·2 in the previous year. By way of contrast I may state that the proportion for England is about 100 males to 79·5 females. It is possible the difference may reflect in some degree the less care likely to be taken of females than males when sickness overtakes them in this country by the uneducated classes. The average difference of 11·5 per cent. between male and female deaths was exceeded in 31 towns, in 19 of which the variation was more than 20 per cent. Whilst this total average rate is decidedly heavy and must imply great avoidable mortality, those for Masulipatam (288), Ellore (299·6), Guntúr (331·1), and Bezwada (333·7) are records of a lamentable loss of infantile life. These towns are within the districts of Kistna and Gódávari, where the inhabitants must have much the same customs and method of treating infants. The only other places outside these districts where the same results are approached are in the crowded and insanitary City of Madras (286·1) and in Tuticorin, which is famous for its brackish and unsatisfactory water-supply (288). Unfortunately, to arrive at a conclusion as to the nature of this large mortality, information such as is not now available in statistics furnished for this report would be necessary; that is, the actual nature of causation of death has to be ascertained, and even then one is confronted with the difficulty that the causation stated by uneducated mothers must be received as sufficient diagnosis by municipal registrars. It is in the investigation of such matters that my suggestion to group registration according as they have been verified by medical diagnosis or not, would have been of peculiar value (G.O., No. 1767 M., dated 26th November, 1903). In the meantime, the matter is one which should engage the attention of the District Medical and Sanitary Officers concerned. As soon as the medical aspects of the question are at disposal, the sanitarian's function could doubtless be exercised with value; but this preliminary is necessary. One of the genuine predisposing causes of "convulsions" which form so frequent a cause of death as registered, amongst native children certainly is the means taken by anxious mothers to prevent them, namely, by producing open and slow-healing wounds subject to contamination by the earthen floors of dwellings by branding them with a red-hot needle on the abdomen; although I think this is less frequent than in former days. If actually these convulsions be proved to be due to tetanus, it would be most desirable to attempt Calmette's preventive treatment by the use of dried anti-tetanic serum powder. This, on the opening of the Serum Section of the King Institute, is a point that will be kept in mind. In any case, disregarding the trite fact that heavy infantile mortality bespeaks a high grade of local insanitary conditions, it is certain that the sanitary reformer and the educationist have before them a duty in securing that native mothers should better understand the care of infants. In such matters, by the spread of knowledge by means of pamphlets, Mrs. Brander, a late Inspectress of Schools, has to my knowledge done much good; but there is ample room for more lady workers.

Chief Diseases.

Cholera.—There was a decline in the incidence of cholera in the population when compared with the previous year, the rate being ·7 against ·8. The districts most severely affected were Madura and Malabar. The conditions in Malabar, in the rural parts, are not at first sight favourable to the spread of cholera, owing to the frequency with which the people reside at distances from each other, and utilize water-supplies which are within the private control of individuals. Nevertheless, there are portions of towns, especially parts inhabited by Moplahs, which present exactly the opposite features; there is much overcrowding and the water-supplies are open to contamination. It is customary for local officials to regard the former condition of affairs as typical of the district, and to hold that sanitary requirements are very few. Guided by such opinions, the Malabar District Board last year (1902-1903) spent under the head of sanitation only 0·23 per cent. of the total revenue against an average of 5·57 per cent. expended for that purpose in the other districts of the Presidency. Whatever impression be conveyed to the

casual observer of scattered residences and ample water-supply, there can be no doubt there is much solid sanitary work that demands attention in this district. Certainly the idea that no special sanitary care is requisite does not seem to fit in with the fact that typhoid appears to have a special predilection for Malabar, and that it returned the heaviest cholera mortality during 1903. The next district in the order of severity of affection is Madura, where the mortality from this cause was 4,422. Possibly, the large number of zamindari villages in this district handicaps local authorities as to efficiency of sanitary control during epidemics. In any case, neither here, nor in any other area affected with cholera under District Boards, is there reason to believe that the Sanitary or Medical Staff employed was sufficient in numbers to cope with the duties on which they were placed.

At Guindy, in the Chingleput district, an interesting outbreak came to my notice. A bricklayer, resident in Mylapore, was attacked with cholera when working in the compound of a public building situated on the banks of the Adyar. He was known to have vomited and purged on the banks of the river. The same night there was rain. In three days cholera made its appearance in the village at Guindy, which obtained its water-supply from a spot about a quarter of a mile below it on the same bank. A temporary water-supply was opened by the people; but 24 deaths in the population of 431 occurred before the epidemic was arrested. With one exception, all cases had used the water up to the date when it was declared infected. It so happened that from the same source the Government House at Guindy was supplied *after filtration* for minor domestic and garden purposes; drinking water being obtainable from a different source. The household was absent during the period, but, although a few servants were present, none of them were attacked. Seeing that this part of the river, in spite of magisterial injunctions to the contrary, is liable to fæcal contamination as well as from the washings of clothing, it certainly is not a spot that can commend itself as a fit source for the water-supply of a large household, notwithstanding its rough filtration and restriction to minor offices. I thought I had obtained in this case an "object lesson" that would not be thrown away upon the local Taluk Board. Therefore, with some confidence that my suggestion would be adopted, I forwarded a scheme for a small-water supply at 10 gallons per head for the village to be derived from a clean subsoil source. Lifting was to be fulfilled by a kerosine oil engine pumping to an elevated iron reservoir, whence it was to be distributed by pipes and taps throughout the village. The Taluk Board of Saidapet was not, however, to be thus hastily disturbed from that state of equanimity with which it has for years regarded sanitary matters. With the District Medical and Sanitary Officer's concurrence, they pointed out that the same well which would have been protected under my scheme was already available for the people, and that "during the prevalence of cholera, the Taluk Board would protect the well from contamination by appointing a watchman." It did not seem to enter into the Taluk Board's calculation to consider this particular well (unprotected mechanically) might be the first contaminated, and be the means of the spread of cholera, notwithstanding the appointment of that constant scapegoat of the sanitary conscience of public bodies, known as the "tank watchman." I quote this little incident, as evidence of the difficulty that is encountered in securing even petty sanitary advance by rural bodies. Although £160 may be regarded as a large sum for a Taluk Board to provide, still it is obvious the arrangement would have represented once and for all a permanent improvement in the village concerned. The upkeep of a kerosine oil engine neither demands great skill nor unreasonable expenditure for fuel. The question of attempting to persuade local bodies to undertake methods of protection of water-supplies by definite mechanical means, instead of by the omniscient tank watchman, has been much pressed by Government in its reviews of reports during 1903, and its importance will, it is hoped, in time force itself upon notice.

In municipalities, the incidence of cholera decreased from a rate of 1 of the previous year to ·9. The towns most severely affected were Salem (9·8), Periyakulam (5), Cochin (4·9). These towns have notoriously evil water-supplies. In Salem, the washing of clothes proceeds at portions of the river above the town from which water is drawn by people for drinking purposes, although during cholera prevalence its use is discouraged. Into this river is discharged much of the drainage of the town, although of late the Municipal Secretary, who is a Certificated Sanitary Inspector, has managed to persuade the Council to divert a considerable amount of it to sewage filters, so as to use the filtrate for farming. At

Periyakulam, the whole washings of the town proceed to the particular part of the river, which forms the chief water-supply. At Cochin, the supply obtainable locally is brackish, and is largely drawn direct from shallow unprotected holes dug in the sandy soil within inhabited areas. The improvement of the water-supply in these three towns has long been considered. In the case of Salem and Periyakulam, the question is chiefly one of finance; whereas, in Cochin, there are certain physical difficulties that have to be overcome. In this latter case, however, the problem of protecting the existing water-supply against both cholera and filariasis (for which the place is notorious) is of the most simple nature: but the Council continue to regard this aspect of the question with apathy. In the meantime, these towns afford good examples of the results of unprotected water-supplies.

So far as the method of spread of cholera is concerned, I see no reason, with further experience, to modify the views expressed by me in my report for 1893 (page 58 *et seq.*). The chances are, irrespective of well-recognised facts following introduction into a locality, that, in certain areas, the cholera microbe exists in water in a modified or feeble condition and that the epidemic appearance is due to enhancement of its virulence following inflow of suitable pabulum especially from the subsoil and possibly from the surface. At any rate, in this Presidency, cholera is confined in certain districts to certain months with clock-like regularity. The bacteriologist has left the sanitarian with no more information than was obtained by Koch originally as to the behaviour of the cholera microbe. It seems to me there is plenty of bacteriological work applicable to epidemiology that should secure attention. As regards distribution, the sacred River Cauvery is obviously an active agent.

Small-pox.—Vaccination is compulsory in all municipalities, and in only 145 of the 379 unions in the total area of 142,121 square miles of the Presidency. The fact, however, that of the total municipal population of 2,406,455 only 0·1 died from small-pox goes to show that, in spite of possible frequent chances of importation, the influence of protection afforded by vaccination is demonstrable. In rural areas, 0·4 per 1,000 (or 14,667) of population died of small-pox, against 0·7 (or 22,926) in the previous year. Of these deaths, 6,984 were below 1 year of age, giving a rate of 6·47 per 1,000 of births; whilst 4,017 were between 1 and 10 years of age, or at the rate of 0·46 per 1,000 of the population of that age. In municipalities, there were 71 deaths of infants below 1 year of age or 0·83 per 1,000 of births, and 127 deaths between 1 and 10 years of age, or at the rate of 0·21 per 1,000 of the population of that age. These figures show clearly the advantage of the more prompt vaccination of infants in municipalities than now occurs in rural areas, and especially the influence of the more uniform protection afforded to children under 10 years of age which necessarily follows. The large mortality of children under 10 years of age from this preventable disease is a matter that has engaged the attention of Government for some time past; and it recently called for a scheme for the reorganisation of the Vaccination Department coupled with compulsory vaccination in rural tracts. This should prove a most valuable reform and should, within a short period of its inauguration, be capable of showing much life-saving power (G.O., No. 1558 L., dated 7th December, 1903).

Plague.—A total of 13,291 deaths from plague was recorded, of which 6,203 were cases of females and 7,088 cases of males. The total rate of mortality in the aggregate population of the districts infected was 0·5. Of this figure, the Bellary district contributes the high rate of 6·2. The districts indigenously affected were Anantapur, Bellary, Coimbatore, Kurnool, the Nilgiris, North Arcot, Salem and South Canara. Plague has therefore acquired possession of the central districts of the Presidency. Fortunately, the epidemic in South Canara has never assumed large proportion, and no spread along the West Coast has yet occurred. As a special report is annually made on the subject by me, it is not necessary here to enter into details. I may, however, state that the policy pursued by the Madras Government has varied little from the commencement of plague in Bombay up to date, except that the great safeguard of early evacuation has been trammelled, so as to give the enemy a decided advantage. The result has been, on the whole, the contesting of the advance of plague inch by inch, as contrasted with a policy that would first permit of its presence being demonstrated and then taking action. The system is not without the drawback of expense; but even omelettes cannot be

made without breaking eggs. During 1902-03, the total spent on behalf of Local Fund Boards and Municipalities under plague charges was Rs. 4,03,927 (£26,928), so that the contribution per head of the population of the Presidency for the year was 2 pies. So far as it is possible to gauge facts, it would seem that in restraining the advance of plague throughout the Presidency, the money demanded is well spent, in that trade and lives are husbanded. Even if it so happens the advance of the disease should prove irresistible, and the weak measure of attempting to restrain the spread of the disease only after it is proved to be actually present be resorted to, instead of attempting to prevent its securing a foothold, which is the leading feature of the existing policy, the chances are considerable that the inimical result upon public funds would be even more marked than at present, as the producer would be more seriously crippled.

In my report of 1902, I invited the attention of Government to the lack of bacteriological knowledge that should prove a safe guide to the sanitarian, with special reference to the theory of "recrudescence," which is, up to date, popular in India in connection with the supposed survival of the microbes on or in the soil. It seems to me that it is important that this question should be thoroughly threshed out by a specially appointed bacteriologist. The technique of such a subject is beset with many difficulties, like other matters that require a certain amount of perseverance to overcome them, but it would be absolutely economical to appoint a specialist capable of working out the subject fully, even if a liberal salary for several months and an honorarium were to be debited to "plague charges." At any rate, from the sanitarian's point of view, it is absurd to go on spending money in disinfecting with such rigour the walls and floors of houses, without full knowledge of the microbe's capability of survival and fitness to increase in such environments. If, for instance, the bacteriologist would relieve the sanitarian as to burden of doubt as to the period of survival of the plague microbe in earthen floors and walls, and especially as to possibility of its "growing through" soil, as apparently on poor grounds maintained by Yersin, it would be a cheap, easy, efficient, rapid and cleanly method to apply the intense heat of the kerosine oil blue flame (8,000—25,000 candle power is easily secured) under air pressure at the end of flexible tubes to all indestructible surfaces, so that by merely painting over them death of the exposed plague microbes would be certain. This I have already shown by bacteriological experiment to be the probable result. But such results, when secured otherwise than on the surface of soil, are rendered dubious by the presence of air and moisture in the interstices, and are far too slow for work in practice. Surely, an answer to the question is worth having and paying for. In every village in this Presidency, kerosine oil could be obtained, whilst the machinery to give air pressure need be but of the most simple nature. The method of recording plague in this Presidency and the passport system enable each case of first appearance of the disease to be traced with fair accuracy. Investigation of records by me for this purpose goes to prove that town after town that has been infected has suffered solely from importation, and not from recrudescence of the disease of a past season; and that, similarly, it by no means follows that a town once infected may be visited again by the disease. The truth seems to be that plague is kept up not by germs retaining their vitality in formerly plague-infected dwellings, but by direct descent through cases that are not detected by the local authorities, either as a result of too early withdrawal of the sanitary staff during the hot season, or its too great attenuation for the purposes of economy, so that there is failure to maintain correct surveillance of the population concerned. Therefore, the idea that plague must exist in this or any other country for a number of years until its cycle has been fulfilled, seems to me altogether theoretical; in practice, an honest appreciation of the fact that the surveillance of the population should be as active during the hot season when plague wanes, as during the cold season when it waxes, would definitely refute an opinion that is an excuse for, and breeds, apathy. Above all things, much more attention seems to be necessary to secure plague-infected clothing than is possible under a mode of disinfection which requires soakage in liquid disinfectants, and its temporary removal from the owner. The best way to secure confidence *and* the clothing of inhabitants is undoubtedly by the use of a good class of steam disinfector, which is capable of doing its work rapidly at the doors of the infected dwellings in front of the owners concerned, so that they find themselves possessed of their clothing without appreciable deterioration. This view the Government of Madras is now attempting to meet and one light steam

disinfector (Alliot and Paton) has already been imported, and it is hoped before next plague season this Presidency will be in possession of a number of light steam portable disinfectors possessed of vacuum and steam pressure arrangements, worked by means of kerosine oil instead of solid fuel. The use of kerosine oil will enable the apparatus to be lightly built, whilst it possesses the advantage of being procurable in every bazaar in the country. Putting aside the risk of being re-infected from foreign areas, I feel convinced that the energetic working of staffs during the hot weather and more effectual arrangements as to disinfection of clothing than at present existing, would render it possible to absolutely stamp out plague. Such statements ignore infection amongst rats. But I have never yet heard of proved recrudescence through rats. There is against this the evidence of the second appearance of plague in Glasgow, but the chances are there as elsewhere fresh importation had occurred. Rats may be trusted not to stop in any place where their lives are unsafe by reason of disease, or are rendered uncomfortable by reason of various appliances to that end used by human beings. Undoubtedly, much of the plague infection of this Presidency has been derived from Mysore, where there is an unusual method of treatment of plague, the chief feature of which has been that no compulsion has been applied. This is closely allied to the so-called "common-sense plague policy." During the year, a conference with the authorities concerned in Madras and in Mysore was held, at which I was present. Although that grade of sanitary co-operation with this Presidency which, it was hoped, would be secured, has not been fully attained in Mysore, the Government of that territory has at least sanctioned a staff, the object of which is to secure inter-communication between Mysore and Madras districts. Nominally, at least, disinfection is now compulsory. It is hoped that, during the ensuing year, Mysore may prove of less danger to Madras than it has hitherto.

Fevers.—In municipalities, the death-rate from fevers was 6·3 against 6·7 in the preceding year, and in districts, 8·4 against 7·7. Having regard to the fact that plague prevailed in certain of the districts, the small variation under the head of "fevers" and absence of a marked increase under "all other causes" bespeak a fair amount of accuracy as to finding cases of plague, and, therefore, the prevention of their being placed under incorrect heads of registration. The town of Madura shows an increase under fevers of 1·2. The Chief Certificated Sanitary Inspector has shown that, in several localities of the town, the anopheles mosquito is present. A possible rise of fever prevalence in this district should be watched for by the local authorities with care. Under the influence of the Periyár project, large tracts of formerly dry land surrounding the town are being placed under wet cultivation. It is possible that the necessary conditions of a human germ bearer and a readily-infected species of anopheles may yet conjointly exist, although at the present time so far as the rural tracts are concerned and statistics disclose, no evil results have occurred. Nevertheless, the necessity throughout this district for carefully getting rid, by efficient drainage, of the water that has fulfilled its function of irrigation should be held in mind. Kurnool shows a decrease of 3.9 of the fever rate. The registration is probably fairly correct when judged by the existence of an increased birth-rate, the total diminished death-rate, and the lack of tendency to quote deaths under any other particular head. This diminution is therefore apparently in direct response to altered conditions as to irrigation surrounding the town. In 1881, when Vice-President of this Municipality, I was able to prove by records in my possession to the Municipal Council that the introduction of malarial fever into the town immediately followed the large use of irrigation in the vicinity, and advised that a zone of a mile radius should be established round the town, in which no wet cultivation should be permitted. Fortunately, the belief deduced from long observation by formerly received authorities as to the influence of moisture on earth and its removal by drainage, which existed at this time, under the impression that the earth contained the germ (which may yet in part be proved correct) made no difference as to the results. On adoption of this measure, a marked fall of the fever rate occurred: but, as years passed, the Council became less strict in observance of the zone and the fever rate increased. Government recently ruled, on a reference by the Collector of the district, that not the mile zone but the whole of municipal limits* should be free of wet cultivation. Cuddapah,

* The change has not materially altered the size of the zone.

which shares with Kurnool the unenviable notoriety of being highly malarious, is also about to secure a dry zone within its municipal limits, which will doubtless prove helpful in restraining the conditions favourable to the incidence of malarial fever. On the opposite, Masulipatam is increasing its wet cultivation in the immediate neighbourhood of the town. I found in pools on its outskirts no lack of anopheles held to be good malaria bearers. Here, the expenditure of considerable capital for conducting drainage on the method employed in Holland would be necessary to secure efficient results: but much valuable land would thereby be rendered arable, and would be an offset to expenditure.

The question of the extent to which malarial fever prevailed in the Madras City has been a matter of medical and sanitary discussion for several years. That malarial fever can be acquired in Black Town is indubitable; but it has been long perceived that the cases recognised as malarial fever and accompanied by enlargement of the spleen did not respond readily to quinine treatment, and pursued a curiously obstinate course. In my own experience, a marked characteristic of this form of Madras fever was the frequency of the occurrence of lobular pneumonia as a complication. Although the subject is yet incomplete, the highly important researches of Captain Donovan, I.M.S., who found certain micro-organisms in the spleen, which have been named after him *Piroplasma Donovani*, and an investigation which subsequently was opened up, under the orders of the Government of India, by Lieutenant Christophers, lately on duty with the Malaria Commission, go to prove that this fever is not malarial but of a type depending upon the presence of the specific bodies discovered by Captain Donovan, of which the nature is not yet fully ascertained. If this enquiry be successful, it will form an important addition to medical science generally, and will prove of special benefit to the City of Madras which has so long suffered from this hitherto misunderstood form of fever.

In June, 1900, I sent a circular inviting all local bodies to take advantage of the discovery of Ross as to the connection between the mosquito and spread of malarial fever, and especially pointed out that, granted the hitherto recognised policy of drainage of large areas was beyond their means, the palliative mode of causing destruction of mosquito larvæ in pools by kerosine and of the germ in the human being by means of quinine, was at least open to them. For this end, they were advised to select areas for experiments. With the exception of the Kurnool District Board, which put aside a sum of Rs. 500 for an experiment, no action of importance followed. This seemed to me greatly due to absence on the spot of persons trained to observing mosquitoes and their larvæ. I consequently, as stated in last report, assembled a class of Sanitary Inspectors at the highly malarious village of Dhone in the Kurnool district, and trained them for the work. Since then, I have attempted to follow up action taken by the men on their return to their municipalities, by means of reports through the chairmen of the municipalities concerned. They were particularly directed to insert in a map of their towns the spots where anopheles pools were found, and ascertain the subsequent influence of their disappearance under their efforts towards destruction, or removal of the water by filling in or draining. With few exceptions, Certificated Sanitary Inspectors have taken up the matter energetically and the Chairmen concerned have encouraged their efforts. Reports of special interest as exhibiting progress have been received from Certificated Sanitary Inspectors G. C. Nallaswami Pillai (Madura); K. Seshagiri Rao (Cuddalore); T. C. Sankara Kurup (Calicut); S. Sitharama Aiyar (Cocanada); T. S. Venkatarama Aiyar (Conjeeveram); M. Venugopalaswami Pillai (Bellary); and S. Velayudam Pillai (Palamcottah). In reviewing progress of efforts towards extermination of malaria (G.O., No. 1343 L., dated 17th December, 1902), the Surgeon-General called the attention of Government to my proposal made to local bodies to select areas for experiment, and suggested that definite orders as to this should be issued. The result has been that Government has directed that funds be allotted by local bodies for experiments in six carefully selected areas, having for their object the extermination of malaria by the conjoint use of mosquito larvæ destruction, administration of quinine to human beings, and minor engineering works.* The officer selected for the duty will work under this Office, and will have attached to him an intelligent engineering subordinate. There are here, therefore, the elements for a thoroughly honest trial of modern methods of dealing with malaria.

* The necessity for a reversion to the ancient policy of making engineering works the first line of defence, is well borne out by Lieutenant Christophers' candid estimate of results secured in Mian Mir (Second Report of the Anti-malarial operation at Mian Mir, 1901-03).

Dysentery and Diarrhœa.—In rural areas, the total average death-rate from dysentery and diarrhœa amounted to 1·1, whereas, in municipalities, it amounted to 4·6; in the former case, the highest figures reached were in the Nilgiris (3·3), in Malabar (2·8) and in Chingleput (2·7). Such rates are, however, small when compared with those obtaining in the municipal towns of Palamcottah (14·9), Tiruvannámalai (11·0), Vizianagram (8·1), Cochin (7·7), Periyakulam (7·5), Coonoor (7·4), Gudiyáttam and Vizagapatam (7·2 each), Tuticorin (7·0), Parlákimedi (6·9), Masulipatam (6·8), Chingleput and Vellore (6·6 each), Tirupati (6·1), and Conjeevaram (6·0). It would serve no good purpose for me in this report to descant upon the individual local causes which lead to these results. It is obvious that the aggregation of human beings upon a site, as found in large towns, is more favourable to the propagation of the causes of diarrhœa and dysentery than in the more thinly populated villages of rural areas, and that defects of water-supply and of badly conserved soils are more liable to exhibit their mark in a locality where certain conditions of natural soil and surface and subsoil drainage exist than in others. The more experience accumulates in reference to these diseases, the more it is evident that a town cannot rely upon abolishing them by simply taking a new supply of water, and that the supply must be so distributed that its inhabitants shall not have recourse to inferior water at intervals, and, even when this is attended to, that the soil must be kept pure, as a result of correctly conceived and correctly carried out conservancy systems. There are eleven towns at the present time which possess expensive water-supply systems in this Presidency to which these criticisms are applicable, whilst in no case can it be said that the conservancy system of any municipal town is complete. It is a curious fact that a people who are possessed of scriptures which are spoken of with reverence by them, and which lay down rules of great hygienic value as to the disposal of human excretions, should find no representative in Municipal Councils that would take up the matter of conservancy seriously. In a town famous for its advance in European education, where the municipal representatives are largely vakils, always profoundly happy at the prospect of a debate at its Council meetings, I found, in a thickly-populated area, up to the door of an important temple, a normal not casual place of easement.

Injuries.—The rate for injuries noted for the year 1902 was maintained during 1903, namely, ·4. As usual, suicides of females were in greater proportion than those of males, namely, 100 of males to 125·3 of females.

All other causes.—Under this most unsatisfactory heading (so far as nosological purposes and the possibility of locating diseases are concerned), 45·9 per cent. of the total mortality was registered. Having regard to the presence of plague in the Presidency, the possibility of an increased number of events being registered by the people under this heading, with the object of getting rid of plague measures, is necessarily of importance to local authorities. Notwithstanding that the total plague cases for the year were 2,496 more than in 1902, the advance under this head, granting there is any necessary connection between the two, does not seem to have been of much importance, namely, 1 per 1,000 more than the former year (9·2). The increase was not confined to districts affected with plague.

Sanitary Works.

Municipalities.—It goes without saying that the possession of a soil free from contamination by rubbish and more especially by human excrement, is of prime importance to the health of a town. In recognition of the value of soil cleanliness, in the present day, many towns in Great Britain do not scruple at great expense to flush narrow court-yards within insanitary areas, at regular intervals. The late Boer war afforded a repetition of a familiar hygienic lesson, by again proving that the uncleanly soil of even temporarily inhabited areas was followed by a distribution by means of dust, flies and water, of the causative agents of diarrhœa, dysentery and typhoid, with the attendant heavy, yet preventable, mortality. Municipal Councils, although undoubtedly improving year by year in recognition of the importance of soil cleanliness, still leave much to be desired in this respect. For instance, in the town of Madura, which has a population of 105,984 and therefore ranks as the second largest town in the Presidency, the number of public latrines

is eight specially built for the purpose (and, in this respect, it is worth remembering that these latrines are usually for males and females in one spot, and, therefore, they should obviously be quoted as four only) together with four brick wall and one mud wall "simple enclosures." It also possesses 12,000 so-called "private latrines," of which, however, only 5,356 (serving a population, say, of 26,780) are cleansed by municipal agency, whilst it is doubtful if any form of systematic cleansing of the remainder really takes place unless that agency be employed. Under such circumstances, a large part of the duty of the night-soil collecting staff consists in perambulating the nooks and corners of inhabited areas. Under this system even if the fæcal matter were removed, it cannot be imagined that it is so fully effected as to leave the soil uncontaminated, and that dust and flies may not serve as distributing agents of pathogenic germs. In quoting the case of Madura, I have merely chosen it for illustration, on account of its large population; its incomplete system of conservancy is but typical of what occurs in a less degree in certain other towns. On the other hand, it must not be thought that advance, however slow, has not been made steadily from year to year. Thus, one of the errors constantly made by Councils is the neglect of the removal of the night-soil in favour of rubbish. Hence, readjustments of staffs demanding an increase of scavengers for night-soil removal and a decrease of sweepers for rubbish removal, usually denote a tendency in the right direction. The use of light tramways, or a suitable adaptation of the Shone system after the Warrington method for rapid removal of night-soil, is within the financial capabilities of some municipalities, but conservatism in favour of lumbering bullock carts will take some time to disappear. During the year, the number of sweepers was decreased from 2,671 to 2,603, whilst that of public scavengers was increased from 1,456 to 1,480. The night-soil carts have been increased from 764 to 867. If the whole mass of the municipal population be regarded, exclusive of Madras City, it is found that, for each 10,000 there are 0·6 Sanitary Inspectors, 3·0 conservancy subordinates, 7·7 public night-soil scavengers, 12·3 municipal scavengers serving private houses and 13·6 sweepers. In 1894, the proportions were 1·2, 2·8, 6·7, 6·1 and 14·3. The Sanitary Inspectors of that year were unqualified, and consequently their reduction in quantity, in favour of the smaller number of Certificated Sanitary Inspectors of the present day, represents no loss.

In reference to disposal of night-soil, there is evidence of advance; its utility for agricultural purposes, notwithstanding caste prejudices, is year by year more fully recognised. Thus, during 1902-03, municipalities realised under rubbish and night-soil disposal the sum of £2,806 against £2,788 in the previous year and £1,518 during 1892-93. In regard to utilisation of sewage there are *promises* that action will be taken by Chingleput, Karúr, Chicacole, Tinnevelly and Bezwada. Kumbakónam, Negapatam, Tanjore, Rajahmundry and the City of Madras continue to secure good financial results by their efforts in this direction. Vizianagram and Vizagapatam, under the stimulating care of the present District Medical and Sanitary Officer Major Vickers, I.M.S., have made specially useful endeavours by diverting sewage from directions where hitherto its effects were harmful. In Tanjore, the net profit from sewage farming was £126; in Madras City it amounted to the sum of £2,402. Modified filter trenches to replace cesspools have been introduced under my advice with success in Cuddalore, Palamcottah and Periyakulam. For the last place, the filter trench principle was also advised for a public latrine with success, and it seems to me by such adaptation economical latrines can be secured.

In the important matter of public water-supplies, beyond the completion of the Cocanada scheme, no advance has been made; nor does there seem any possibility of any town undertaking a scheme of any sanitary importance until Government is in a position to again offer grants-in-aid, which usually amounted to one-half the capital to be sunk. As an alternative, seeing that the financial condition of most municipal towns is sound, it seems to me it ought to be possible, by Councils putting their wants before English investors, to secure English capital on the security of taxes for investment. There is, of course, no lack of capital in this country that might be thus suitably invested, but the Indian capitalist's estimate of what is a fair return for his money is warped by his experience of the profit of money-lending.

With the advance of plague, it is probable that more attention will be given by municipalities to the condition of overcrowded localities than hitherto. Bad

examples of these are in Rajahmundry, Madura, Tinnevelly, Negapatam, Coimbatore and Ootacamund. Improvement schemes are in course of preparation in all these localities. Under Mr. Pears, the present President of the Municipal Commission, City of Madras, the subject is also receiving attention in respect to the notoriously insanitary locality known as the Tinnevelly Settlement.

During the year, Government undertook the amendment of the City of Madras Municipal Act. The introduction of several efficient sanitary clauses is contemplated.

Attached is the usual table (Appendix XI.), showing the results of completed sanitary works on public health. As to the six towns with protected water-supply, where distribution is fairly efficient, the following average figures are obtained :— For five years previous to the introduction of water-supply, the average cholera rate was 4·1; for the five years ending 1903 it was 1·4 and, during 1903, 1·3. The fever death-rate for five years prior to the introduction of water-supply was 8.9; in the five years ending 1903 it was 4·4, and in 1903, 3·6. The total death-rate for five years prior to introduction of water-supply was 30·4; for the five years ending 1903 it was 27, and in 1903 it was 27·6. Under these circumstances, I do not think there is any reason to doubt that the introduction of protected water-supplies (although not in a single instance in this Presidency can it be said that it has been so fully introduced into a town to the exclusion of other sources that its full benefits could be derived by the population) has been followed by a marked reduction in total mortality, and in the fever and cholera rates. In other parts of India, I am aware it is held that the introduction of water-supply into towns when unattended with a drainage system, as is the case in this Presidency, has been followed by an increase of the fever-rate, and it is of course no stretch of theory to ascribe exacerbation to better opportunities for propagation of the anopheles mosquitoes. However, statistics have continued now for some years past to teach the one lesson that, with the introduction of improved water sources in this Presidency, a diminution of fever-rate has followed. It has been long felt by the medical profession that there prevail amongst the people still imperfectly recognised forms of fever, and it is quite possible that certain of these are connected with the water-supply. For example, we know nothing of the real origin of the *Piroplasma Donovani*, and it may happen this may be proved to be connected with the water-supply, or that the theory that water-supply is connected with malarial fever has still truth in it, notwithstanding the clear demonstration that it is certainly capable of being propagated by transfer by mosquitoes from man to man. In respect to the fever-rate, it is worth remembering that there may be less inclination during the period of plague prevalence to register deaths to be due to "fever"; but how little this possibility need be taken into account can be judged by contrasting the conditions of towns where protected water-supplies have not been introduced. Here, we find that in 14 towns the average fever-rate for the five years ending 1898 was 6·7 and for the same period ending 1903 5·9; a reduction of ·9, against 4·5 in the case of the towns supplied with water. Moreover, the total mortality, far from being reduced, rose from 29·4 to 30·0. Although, therefore, I think that the towns that are now supplied with water by no means have obtained the maximum benefit they should secure for the money they have spent, were they to arrange for more perfect distribution and for the closing of all promiscuous water sources, it seems to me evident that the populations in decreased mortality are already reaping the benefit that should compensate for the inconvenience caused by increased taxation. There is, I believe, room for reform in the matter of supplying houses with water. It is rarely necessary for native houses on account of a climate of the character of the South of India, or on account of caste, to require distribution of the water in private premises beyond the reach of ready inspection. When distribution of this nature is necessary, it should be paid for as a luxury, and thus both economy of water and its purity would be controlled better than at present. Unfortunately, no real effort to secure economy of water by Councils seems to be made beyond shutting off the water supply for a certain number of hours daily—thus causing all the danger of intermittent supplies. Beyond the Cocanada water-works already referred to, which were opened in July, 1903, no new major sanitary works were completed during the year.

District Boards.—I regret I have nothing to record as to advance by District Boards that would appeal to the average sanitarian. The people under the administration of these Boards number 34,598,644 against 2,406,455 in municipalities.

The total income of these Boards (1902-03) amounted to £643,817. Of this amount, if the total income after meeting "plague charges" be regarded as that solely available, 5·4 was spent on sanitation, as contrasted with 7·2 per cent. on education (irrespective of £141,627* from Provincial Funds) and 8·5 on medical services. In the midst of a population larger than that of England and Wales, the expenditure in obtaining new sources of water-supply, which are certainly most urgently required, amounted to ·1 pie per head. In not a single village, up to date, is there any pretence towards public water-supplies delivered in protected pipes by lifting or by gravitation, after modern methods. Aeromotors and kerosine oil engines are, at the present time, cheap, and require but modest skill for their use, whilst the possibility of landing pipes in rural parts by rail and canal is now infinitely better than 30 years back; yet, District Boards continue to forget that to protect their water-supplies by less crude methods than at that period might reasonably be expected of them. The remainder of the 5·3 per cent. of the total funds was spent in *repairing* old wells and tanks, in conserving 399 unions and 140 villages, and in the sanitation of fairs and festivals. The absence of new sanitary works to which I have invited attention is in the main due to the Cinderella share that sanitation receives from the income of Boards, but also to the absence of officers who have the time to devote to not only suggesting but drawing up the main outlines of simple schemes. Much may be hoped for in the future in initiating small and useful sanitary schemes, by Government having sanctioned the employment of District Health Officers of the Assistant Surgeon Class (G.O., No. 1558 L., dated 7th December, 1903). These men, I have recently proposed to Government, should be required to take the "Licentiate of Sanitary Science" degree of the University of Madras. They would be aided by competent engineering subordinates. The appointments now sanctioned form an important link in the scheme some years back placed by me for consideration before Government in which Vaccination, Sanitation and Registration of rural areas were placed under the administration of a single Sanitary Department (G.O., No. 435, Public, dated 17th April, 1897). All hopes of such an advance have, however, been aborted by Government which had hitherto fostered the growth of a movement to supply the Presidency with Certificated Sanitary Inspectors suddenly forbidding their use in rural areas in permanent posts, on the ground that their employment "with a roving commission to point out sanitary defects in villages would be attended with grave danger," and that "their right to recommend or report would furnish a powerful weapon for misconduct" (G.O., No. 1131 L., dated 11th September, 1903). Although the same Order secured an improvement in the education of Sanitary Inspectors by giving them a course in Sanitary Engineering, the conditions brought about by it are such as to react generally upon sanitary advance in rural areas. Not only has this Order operated in this manner, but it will undoubtedly greatly limit the outturn of Sanitary Inspectors. It has already rendered the supply of certificated men for plague duty a matter of difficulty.

---

* This is the figure for 1901–02.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER FOR BOMBAY, FOR 1903.

(*Lieutenant-Colonel O. H. Channer, I.M.S.*)

General Population.

European and Eurasian Vital Statistics.

The European Census population of 1901 in the Bombay Presidency, exclusive of cantonments in quasi-foreign territory, is 18,804. During the year 1903, 270 births and 253 deaths were recorded against 251 and 302, respectively, in 1902. The birth-ratio was 14·36 as against 13·35 in 1902, the death-ratio 13·45 as against 16·06 in 1902. By sexes 132 males and 138 females were born against 133 and 118 in 1902. And as regards deaths 148 males and 105 females died against 189 and 113 in 1902.

The Eurasian Census population of 1901 is 6,557. During the year 139 births were registered against 140 in 1902, and 160 deaths against 154, the birth-ratios being 21·20 per 1,000 against 21·35 in 1902, and the death-ratios 24·40 against 23·49. Of those born 63 were males and 76 females against 68 and 72 in 1902. As regards deaths 82 males and 78 females died against 84 and 70 in 1902.

Native Population—Vital Statistics.

Births.—In the Presidency of Bombay, including Sind, during the year 1903, there were 576,949 births registered against 631,393 in 1902, less by 54,444 than the number registered in the previous year and also less by 42,231 than the decennial mean ending 1902. In only six districts, Thána, Kolába, Ratnágiri, Sukkur, Panch, Maháls and Upper Sind Frontier, did the number of births exceed the deaths. The recorded birth-rate for the year was 31·22 per 1,000 against 34·16 in 1902 and a decennial mean of 32·98. The number of births recorded during the year is less in every Collectorate than in the previous year except in Belgaum, Dhárwár, Bijápur and the Upper Sind Frontier.

There were 299,485 male and 277,464 female births recorded during the year against 327,549 and 303,844 in 1902. For every 100 female births there were 107·94 male, which results compared with those of European countries is encouraging as denoting considerable accuracy in the registration of the sexes. There is a tendency, however, to slightly favour the males.

The following statement shows the number of births recorded in each year since 1893:—

Year.	Number of Births.	Year.	Number of Births.	Year.	Number of Births.
1893	664,305	1897	629,693	1901	465,647
1894	660,268	1898	582,371	1902	631,393
1895	674,304	1899	685,348	1903	576,949
1896	691,847	1900	505,662		

Since 1896 these figures show the effects of the havoc caused by plague and famine.

Fecundity was highest in November, lowest in February. In 1902 it was highest in October and lowest in February, whilst for the decennial 1893 to 1902 the maximum fecundity shows October to be the favourable month and February the lowest.

The recorded birth-rates among the urban and rural populations of the Presidency were 23·56 and 32·37 against 27·09 and 35·23 in 1902. Except in the Collectorates of Dhárwár, Kánara and throughout Sind, except the Upper Sind Frontier, the rural birth-rates exceeded the urban. In Dhárwár and the Upper Sind Frontier the birth-rates were nearly the same, viz., 31·12 and 22·93, respectively, in the rural and 31·94 and 22·10 in the urban. The urban rates in the collectorates of Násik, Ahmednagar, Poona, Sholápur, Ratnágiri, Thar and Párkar are all below 17 per 1,000 whilst in Sind both urban and rural rates are extremely low with the exception of urban Karáchi where births are very well recorded (44·35) and urban Sukkur (37·46). The mortality of women at a child-bearing age from plague and the havoc caused by that disease especially amongst the urban populations together with the scattering of the population outside towns and villages, both lowered the birth-rates and made registration often extremely difficult.

Out of 56 towns and 7 cantonments in the Presidency 3 towns recorded a birth-rate exceeding 40 per 1,000, viz., Karáchi (44·35), Sukkur (40·01) and Borsad (42·07). Eleven towns returned rates between 30 and 40, 28 between 20 and 30, and the remainder 14 towns and 7 cantonments below 20. Whilst plague created great disturbance in the correct registration of births, municipalities have much work before them before their birth returns can be accepted as accurate. The municipalities of Karáchi, Sukkur and Borsad are to be congratulated on the care with which they have carried out their duties.

Deaths.—Among the native population in the rural, town and cantonment circles in the Presidency 811,525 deaths were registered in 1903 as against 721,462 or 90,063 more than in 1902. Of the total deaths no less than 281,269 or 34·66 per cent. were due to plague. Of the total deaths registered 413,783 occurred among males and 397,742 among females against 369,491 and 351,971, respectively, in 1902.

The following statement shows the number of deaths recorded in each year since 1893:—

Year.	Number of Deaths.	Year.	Number of Deaths.	Year.	Number of Deaths.
1893	511,831	1897	749,916	1901	686,134
1894	607,179	1898	548,825	1902	721,462
1895	538,540	1899	672,269	1903	811,525
1896	596,472	1900	1,318,783		

Death-rate.—The death-rate reached the very high proportion of 43·91 per 1,000 and rose above that of 1902 by 4·87.

The rate per 1,000 of males dying to males living was 43·42 and of females dying to females living 44·43. In 1902 these ratios were 38·77 and 39·32, respectively. For every 100 female deaths there were 104·03 of males, but these proportions vary considerably, as in Bombay City the ratio of males to female deaths was 133·79, in Karáchi Collectorate 120·27 and in Násik 105·72.

In the Western, Central, Southern, Gujarát and Sind Registration Districts the number of deaths recorded in 1903 were 192,649, 217,255, 207,903, 124,652 and 69,066, and their ratios per 1,000 were 43·60, 44·70, 63·10, 46·15 and 21·54, respectively. Excluding Sind the ratios were greatly inflated by plague, 18·39 per 1,000 of population being destroyed in the Central, 32·85 in the Southern, 11·16 in Gujarát and 11·50 in the Western Registration District.

Excessive death-rates were recorded in all collectorates excepting those of Sind, and Panch Maháls and Ratnágiri and ranged from 74·53 per 1,000 in Belgaum to 29·38 per 1,000 in Kolába. 14 out of the 19 collectorates of the Presidency proper recorded rates over 40 per 1,000. The exceptionally low death-rates recorded in

the Thar and Párkar and Upper Sind Frontier Collectorates, 17.95 and 15.19, respectively, point to defective registration.

As regards deaths by ages there were 220,404 deaths of children under 5 years of age which, according to the census of 1901, gives the high death-rate of 97·04 per 1,000 on the population under 5 years. The children under five contributed 27·16 per cent. to the total deaths. The deaths of adults, 20-30 years of age, were also excessive. The influence of the destructive plague epidemic during the year is seen throughout the mortality exhibited in this table.

The mortality was excessive for the whole Presidency in both sexes, viz., 219·57 and 206·70 per 1,000 births, respectively, and may be ascribed in great measure to bad sanitary arrangements and those special agencies which destroy infant life and which vary in different localities. Some of the principal causes are improper and insufficient food, bad management, use of opiates, neglect, early marriages and debility of mothers. The widespread influence of plague struck severely both mothers and infants. All districts show abnormal rates except Ratnágiri, the Panch Mahál and the Upper Sind Frontier where the mortality was recorded as below 150 per 1,000 births. In the remaining Collectorates, excluding Bombay, the rates reach as high as 301·09 male and 288·97 female in Broach to 162·88 male and 141·15 female in Bijápur. In Bombay City the ratios returned each 547·48 and 527·57, respectively. The causes of the apparent excessive mortality of infants in Bombay City and Ahmedabad were specially reported on in accordance with Government Resolution No. 3184, dated 19th June, 1903.

Deaths by causes.—The subjoined table shows the deaths in 1903 arranged according to causes and contrasted with the results for 1902 and with the mean of the preceding five years:—

Causes of deaths.	Mean for 5 years, 1898–1902.		1902.		1903.	
	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.	Number.	Ratio per 1,000 of population.
Cholera	38,733	2·07	3,229	·17	1,825	·09
Small-pox	4,239	·23	2,189	·12	2,732	·15
Plague	105,799	5·66	184,752	10·00	281,269	15·22
Fevers	310,175	16·60	270,845	14·66	259,704	14·05
Dysentery and diarrhœa ...	93,730	5·02	58,682	3·17	55,443	3·00
Respiratory diseases	—	—	59,379	3·21	59,349	3·21
Injuries	7,367	·39	7,434	·40	6,693	·37
Other causes	229,452	12·28	134,952	7·30	144,510	7·82
All causes	789,495	42·25	721,462	39·04	811,525	43·91

The maximum mortality (92,785) occurred in January and the minimum (38,803) in June. In 1902 the maximum and minimum occurred in December and June, respectively (85,005) and (34,462).

The recorded death-rates among the urban and rural population were, respectively, 59·87 and 41·51 per 1,000 as against 60·22 and 35·85 in 1902. Only in six collectorates out of 25 were the rural death-rates in excess of the urban.

Chief Diseases.

Cholera.—In the year 1903 there were 1,825 deaths recorded as due to cholera compared with 3,229 in 1902. The disease was practically confined to Sind where

there was a slight but distinct epidemic. In nine districts in the Presidency proper only 73 deaths were recorded. The epidemic which last year caused 3,229 deaths was also practically confined to Sind which bore 95·41 per cent. of the total cholera mortality. In the year under report, 96·00 per cent. of the mortality likewise occurred in this province, whilst nine districts recorded the remaining deaths.

During the first four months of the year, the disease was absent from the whole Presidency excepting in Bombay City (5 deaths) and a single death recorded from Broach Town. From May to October the cholera poison became active in Sind alone, and was chiefly confined to the Sukkur, Lárkhána and Upper Sind Frontier Districts. In the terrific heats of June, July and August the disease was at its worst, destroying 1,141 persons or 65·12 per cent. of the total mortality during the epidemic.

There is a distinct relation between cholera and seasons. In the rainless province of Sind the seasons differ from those of the Presidency in their excessive high temperatures in the hot months and the very great alternations in the cold. The air is very dry. In the epidemic which occurred in Sind, the disease was active from May to October and was at its maximum during the hottest months of this period—June—August. In the epidemic of 1902 it showed the same seasonal prevalence.

The following table shows the total number of deaths from cholera in each of the twenty-one years ending 1903:—

Year.	Number of deaths.	Year.	Number of deaths.	Year.	Number of deaths.
1883	37,954	1890	3,259	1897	57,109
1884	13,804	1891	17,850	1898	4,368
1885	37,287	1892	42,900	1899	8,579
1886	167	1893	18,853	1900	163,889
1887	25,711	1894	33,588	1901	13,600
1888	36,500	1895	8,890	1902	3,229
1889	32,431	1896	35,404	1903	1,825

This record shows that cholera is indeed endemic in the Presidency lighting up into epidemic lasting generally three years. If the deaths are multiplied by 2 on the assumption of the general cholera mortality being 50 per cent., some idea may be formed of the terrible amount of sickness and suffering caused by this disease.

Fifty-two per cent. of the collectorates returned cases, but in only three districts of Sind, viz., Sukkur, Lárkhána and Upper Sind Frontier was the disease epidemic. Karáchi, which recorded an outbreak destroying 4·47 per 1,000 of population last year was entirely free in 1903. The mortality in Sukkur was 1·24, in Lárkhána 1·39 and in the Upper Sind Frontier 0·56 per 1,000 of population.

Out of 56 town circles in the Presidency, 10 were affected by cholera against 8 last year. The disease was trivial in Belgaum, Nagar, Bijápur and Broach with a single death in each. Poona returned but 2 deaths, whilst Bombay City was particularly free from the disease with only 17 deaths. The chief mortality occurred in Shikárpur (2·30), Sukkur (2·65), Lárkhána (2·54) and Jacobabad (3·08) per 1,000 of population.

No cholera occurred in any of the 7 cantonments in the Presidency.

The disease was very local, attacking but 160 out of 25,846 villages in the whole Presidency, and of these, 152 or 95 per cent. were in Sind.

Small-pox.—There were 2,732 deaths from small-pox (1,488 males and 1,244 females) against 2,189 in 1902 and a decennial mean of 4,049. Of the 2,732 deaths, 1,460 or 53·44 per cent. were contributed by the city of Bombay. The total mortality was considerably below the mean. Assuming amongst the vaccinated and unvaccinated 30 attacks to each death, there were some 81,960 persons attacked from the disease during the year. The highest mortality occurred in the city of Bombay with 1,460 deaths. The Western Registration District contributed 734, the Central 203, the Southern 53, Gujarát 53 and Sind 229. The disease was conspicuous in the

Hyderabad, Ratnágiri, Kolába, Násik and Khándesh Districts. In the year under report 29·87 per cent. of deaths occurred among children under 1 year of age, 39·60 among children 1-10 years old, while the remaining 30·53 per cent. took place among persons over 10 years of age.

The disease is endemic. The figures of previous years show the destruction caused year by year by this essentially preventable disease. As an instance of the difficulty in preventing the spread of the disease, the Deputy Sanitary Commissioner, Sind, observes: "There being no jurisdiction over the movements of infected persons either by road or boat the disease is carried from one circle to another in the province. In a particularly severe outbreak in the town of Málegaon, Western Registration District, the Deputy Sanitary Commissioner draws attention to the opposition to vaccination on the part of a class of local Momins, weavers, and the difficulty in obtaining early notification of the disease from neglect on the part of the people in reporting cases to the town authorities. The spread of the disease in Málegaon was mainly due to this cause and the opposition of the Momin weavers.

The Deputy Sanitary Commissioner, Southern Registration District, observes: "Parents in the jungle districts of Kánara and Dhárwár object most strongly to vaccination especially of infants under 1 year of age, thus many children escape vaccination permanently."

The preventive measures adopted in all outbreaks were those habitually adopted by the Department, viz.:

On the notification of outbreaks, vaccination and revaccination is offered to the people and as much vaccination work performed in and around the affected area as possible. Isolation and disinfection methods are at present impracticable. Owing to notification being non-compulsory frequently the only intimation received by the Deputy Sanitary Commissioner is the return of deaths from small-pox, by which time the disease has obtained a firm hold on the village. In the Málegaon outbreak above referred to, the Deputy Sanitary Commissioner states on visiting the town he found that "for the most part only fatal cases had been reported." The only remedy of any use in dealing with small-pox is the gradual introduction of compulsory vaccination and registration with compulsory notification of cases, all other methods are merely palliative.

Fever.—There were 259,704 deaths registered under the heading "Fever" (134,048 males and 125,656 females) against 270,845 in the last year and a decennial mean of 354,577. The total fever death-rate for the whole Presidency was 14·05 per 1,000 as compared with 14·66 last year, and the decennial mean of 18·91 per 1,000. The highest mortality from fevers was recorded in Ahmedabad (31·19), Broach (24·83), Lárkhána (21·51) and Surat (18·14). All the districts in Gujarát and Sind (except Sukkur) and the collectorates of Khándesh, Poona, Sholápur, Kánara and the city of Bombay recorded lower rates than last year. The remaining districts showed higher rates—Násik excepted, in which they are equal. The number of deaths returned as due to fevers was highest in January and lowest in June. They rose steadily from August to January and gradually fell from 24,045 in March to 15,773 in July.

In accordance with the Army Sanitary Commission's memorandum on the Sanitary Commissioner's Report for 1901, paragraph 1, a brief account is given of the measures carried on in dealing with "Malarial Fevers." The Deputy Sanitary Commissioner, Southern Registration District, remarks "Malaria is especially ripe in the forest areas of Kánara and Dhárwár. The Collector states the population in these areas is gradually diminishing." Captain Hutchinson mentions quinine is at present issued at dispensaries and post offices and also by Circle Inspectors, and now travelling dispensaries have been sanctioned for the most malarious areas in Kánara. An attempt at the reduction of mosquitoes in the forest areas he considers impracticable. In Bijápur Town Captain Hooton, Civil Surgeon, organised mosquito brigades with good effect especially in the vicinity of the Jail. Londa, Belgaum and other places were being dealt with in a similar manner. In Násik, Lieut.-Colonel Anderson, Deputy Sanitary Commissioner, obtained encouraging results from the destruction of the breeding ground of anopheles, and as long as he could be present the work was energetically carried out.

Plague.—During the year 1903, 281,269 deaths (141,559 males and 139,710 females) were recorded from plague, being an increase of 96,517 compared with the previous year.

The number of deaths ascribed to plague in each year since 1896 is as follows:—

Year.	Number of deaths from Plague.	Year.	Number of deaths from Plague.
1896	2,086	1900	33,196
1897	46,944	1901	128,259
1898	86,191	1902	184,752
1899	96,596	1903	281,269
Total	231,817	Total	627,476
Mean	57,954	Mean	156,869

As will be seen from the table the disease was extremely fatal in 1903 destroying over a quarter of a million persons. The mortality was the highest experienced since the commencement of the disease in 1896 and affected all districts more or less except Thar and Párkar and the Upper Sind Frontier.

Excessive mortality fell on the collectorates of Belgaum and Dhárwár. No less than 92,043 or 32·72 per cent. of the total plague mortality occurred in these ill-fated zillahs. 222 or 78·44 per cent. Registration Circles were attacked. Excluding Sind the percentage was 93·75. The rates per 1,000 of population for the different Registration Districts were as follows:—Southern, 32·85; Western, 11·50; Central, 18·39; Gujárat, 11·16; and Sind, ·85.

The disease, which rose steadily last year from July, continued severe through the first quarter of 1903, when the mortality fell from 32,188 in March to 17,571 in April. Through May and June the mortality showed marked decline and thence onwards steadily increased to October gradually falling in November and December. In both 1902 and 1903 the mortality from plague have been the highest on record. In both years there was the same remarkable fall in the deaths during May and June.

Notwithstanding the widespread and fatal character of this scourge only 18·27 per cent. of towns and villages were affected as against 10·38 per cent. last year.

The general rates were markedly affected by plague in the districts of Khándesh, Násik, Ahmednagar, Poona, Sholápur, Sátára, Surat, Kaira and all the districts of the Southern Registration District except Kánara. In the towns plague was the cause of over half the general mortality in Nasirabad, Yeola, Ahmednagar, Poona, Sholápur, Sátára and Karád and in the remaining towns greatly raised the general death-rates.

Dysentery and Diarrhœa.—Dysentery and Diarrhœa caused the deaths of 29,586 males and 25,857 females, or a total of 55,443 persons as against 58,682 in 1902 and a decennial mean of 69,364.

The deaths ascribed to dysentery and diarrhœa which were so numerous during the famine years, notably in 1900 when the mortality was 218,243, fell to 55,443 in 1903. The causes of the high annual mortality from dysentery and diarrhœa must be ascribed chiefly to impure water-supplies, poverty, privation, unwholesome food, dust, flies, and lack of skilful medical attendance. Travelling dispensaries would do much to lessen the high mortality from these diseases.

The Deputy Sanitary Commissioner, Gujarát Registration District, remarks: "Strict attention to the purity of the drinking water-supplies is the chief prophylactic to apply to the prevention of these diseases. As far as I have observed during the short period I have been in Gujarát, but little attention is paid to prevent contamination of drinking water-supplies, practically no attention being paid to the recommendations of the Sanitary Department on the subject."

The mortality was highest in the Western Registration District, 5·30 per 1,000, and lowest in Sind, ·18. The Central returned a ratio of 4·35, the Southern 2·59 and Gujarát ·65 per 1,000.

Injuries.—During 1903, 3,723 males and 2,970 females met with violent deaths against 4,107 males and 3,327 females last year. The mortality from these causes was the lowest since 1897. Of the 6,693 deaths, 3,040 occurred from drowning, 1,074 from snake bite, 828 from wounding, 172 from hanging, 132 from poisoning, and 79 from attacks by wild beasts.

Respiratory Diseases.—The total deaths from respiratory diseases amounted to 2·52 per 1,000, whilst in towns it was 7·83. High mortality rates were reported from the towns of Ahmednagar (15·54), Bombay City (9·30), and the Gujarát towns of Surat (17·79), Broach (19·69), Jambusar (25·23), Kaira (20·27), Nadiad (12·22), Borsad (10·54), Kapadvanj (13·44), Ahmedabad (10·50). Hyderabad (Sind) had the very high rate of 14·28 per 1,000. The returns from towns of Gujarát are unusually high, and if correct, would indicate a considerable amount of lung disease.

Other Causes.—The number of deaths recorded from "Other Causes" number 144,510 (71,953 males and 72,557 females) against 134,952 in 1902 and a decennial mean of 161,830. 17·87 of the total deaths were recorded under "Other Causes."

Sanitary Works.

During the year ending 31st March, 1903, there were 166 municipalities in the mofussil with a population of, according to the Census of 1901, 2,376,275 souls. The total net income of these municipalities amounted to £398,960, of which sum £106,042 was expended on improving water-supply, drainage and conservancy within municipal limits. The ravages of plague have embarrassed the financial position of most municipalities, and for want of funds many urgent schemes of water-supply and drainage have not been carried out.

There were 23 District Local Boards with 207 Táluka Local Boards; the entire income of these Boards during the year ending 31st March, 1903, amounted to £326,463, and out of this sum £15,718 was expended on water-supply and drainage.

The Bombay Village Sanitation Act, 1889, has been introduced into 265 villages against 294 up to the end of last year, this decrease being due to the abolition of 37 non-working committees in the Poona Collectorate as per Government Resolution, General Department, No. 6107 of 23rd November, 1903.

The number of selected villages in which "The Village Sanitary Inspection Book" has been introduced stands at 3,598; of which 1,818 or 51 per cent. have been written up by officers of the Sanitary Department.

The death-rates in all the towns enumerated have been greatly affected by plague, since the introduction of either water supplies, or drainage or both. To elucidate the effect of these sanitary measures, detailed inquiry and report is required for each town, especially with reference to fever and plague mortality.

General Remarks.

The widespread and destructive epidemic of plague in 1903 crippled many of the municipalities, and one cannot but have the deepest sympathy with the people of those towns which suffered so terribly from the pestilence. It was the most destructive plague year since 1896. Nevertheless, it is gratifying to note that the closing balance of the municipality in the Presidency was £98,440, and that the amount spent on public health and convenience was £182,440 or 40·74 per cent. of income and showed an increase of £21,024 over last year.

The extension of towns and villages over a larger area than at present is imperative. The extreme density of the population on the inhabited area and the insanitary conditions engendered thereby are patent causes of disease. It is no wonder, then, that the malignant plague bacillus has found the undefended and overcrowded population such an easy prey. The lesson to be learnt is obvious—the people must spread into suburbs and live more in the country and sooner or later land must be taken up for this purpose. Already in many towns the people are beginning to see the value of living in suburbs, as *e.g.*, in Bombay, Belgaum, Poona, &c.

The registration of vital and mortal statistics still remains defective in Sind, and many of the towns of the Presidency proper. Municipalities are timid in the

enforcements of by-laws. The vaccinators who are employed to check the birth and death registers and report omissions to their Deputy Sanitary Commissioner, for fear of offending and bringing to punishment the police patels who are the registrars, perform this duty in a very perfunctory manner. As the registrar is also the official upon whom the vaccinator depends for his success in vaccination work, it is obviously his interest to keep in with that official. Hence omissions in the birth and death registers are not to any extent reported by vaccinators.

Registration might be improved in dispensary towns if the work could be handed over to the Medical Officer, who should also be made Medical Officer of Health of town and grant medical certificates of the cause of death.

The high rates of "still-born" in the Bombay City, Ahmedabad and Kánara have from time to time attracted attention. No definition of "still-born" has ever been given as a guide to Registrars so far as I am aware. In Italy, Germany, and the four Scandinavian countries the term "still-born" is used in the medico-legal sense, *i.e.*, a viable infant (having had over six months of intra-uterine life, being 25 centimetres long) which is dead without having breathed. In this country the report of "still-born" is received generally second-hand by Registrars and in consequence the information is often inaccurate.

The inoculation of children with cow-pox from arm to arm is not always a very simple operation, especially with refractory children. When, as we know, blood is not infrequently mixed with the vaccine the necessity for maintaining a strict supervision over operation by Inspectors and Deputy Sanitary Commissioners must be conceded. It is hardly justifiable to perform the vaccination work without. In the Bombay Presidency and Sind there are but five Deputy Sanitary Commissioners to supervise the work amongst 25,424,235 persons covering an area of 188,745 square miles. Frequent changes in this staff must act detrimentally on the supervision of the work. Statistics show the necessity for continued effort in dealing with that highly infectious disease, small-pox, and any relaxation of supervision entails lax work on the part of vaccinators and an eventual increase of the disease.

"Sanitary Inspection Books" have been introduced into a large number of towns and villages, and the results are being watched with interest. Deputy Sanitary Commissioners have been requested to give as much time to them as possible. In Broach they have been introduced throughout the district. It appears to me these Inspection Books which take much time and care to write up, involving also a careful inspection of the locality, should be only introduced at first into the larger and more important towns and villages.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF THE PORT OF BOMBAY FOR THE YEAR ENDING 31ST DECEMBER, 1903.

Summary.—The following statement shows that during the year 14,597 vessels of all sorts, with 719,322 crew and passengers, were examined against 15,432 vessels, with 701,964 crew and passengers during the year preceding. The clothing and bedding of 96,188 crew and passengers of outgoing and incoming vessels were disinfected. Of this latter number 84,287 were native crew and third class or deck passengers and pilgrims who left the port of Bombay for ports out of India, and 11,901 were crew, troops, pilgrims and passengers who arrived by vessels on which cases of infectious diseases occurred or by ships from ports against which the inspection at Bombay was compulsory. Of the 11,901 persons as shown above 2,712 were crew and British troops who arrived by transports, 729 were crew and passengers from East African ports among whom cases of jigger were detected, 6,466 were pilgrims who returned from Mecca via Aden and other routes and whose clothing and bedding had to be disinfected in accordance with the orders of the Government of India, and the remaining 1,994 were crew and passengers of other inward vessels among whom cases of infectious diseases were detected. Fifty-five vessels on which cases of infectious diseases occurred were disinfected. Four hundred and fifty-eight persons among whom cases of small-pox occurred were vaccinated. At the outward and inward inspections and on board vessels lying in the harbour and docks, 77 cases of plague, two cases of cholera, 238 cases of small-pox, 19 cases of measles, 81 cases of chicken-pox, seven cases of jigger and one case of scarlatina were detected.

Statement showing the summary of the shipping of the Bombay Port and the work in connection therewith for the year ending 31st December, 1903:—

Vessels, including Country Craft.	Total Number of Vessels.	Number of Vessels inspected.	Number of Persons inspected, including crew on vessels.	Number of Native Crew and 3rd Class or deck passengers disinfected during the year.	Number of Vessels disinfected.	Number of Persons vaccinated.	Diseases and Number of Cases of each.							
							Plague.	Cholera.	Small-pox.	Measles.	Chicken-pox.	Jigger.	Leprosy.	Scarlatina.

* These figures are supplied by the Customs Department and the Port Officer, Bombay.

Incoming Vessels.—In accordance with the rules in force incoming vessels which were actually infected or suspected to be infected with plague, cholera, small-pox, measles, or other infectious diseases were inspected and disinfected on arrival at Bombay. In the case of all vessels arriving from East African ports medical inspection of their crew and passengers for the detection of jigger and sleeping sickness was carried out. One hundred and two vessels of all sorts with 7,912 crew and 14,360 passengers were inspected on arrival. Of the 102 vessels 23 entered the harbour with cases of infectious diseases on board. Five of the 23 infected vessels were hired transports which arrived from Southampton, Malta, Suez and Aden with a crew of 878 persons and 1,834 troops. One of the transports had two cases of plague, the second had three cases of small-pox, the third had two cases of chicken-pox, the fourth and fifth had seven cases of measles among the crew and troops. The plague-infected transport was the "Sátára" which arrived in February. One of

the saloon crew died of plague during the voyage. Another man was found on arrival to be suffering from fever. He was sent to the Modikhana Hospital where he developed plague. The vessel was infested with rats. On 25th February two dead rats were seen and five on the 27th under the stores on the main deck. The disinfection of the transports and of the clothing and bedding belonging to the crews and troops were carried out under the supervision of the Port Health Officer. Four vessels arrived with seven cases of jigger on board. The cases were removed to the Goculdas Tejpal Hospital for treatment. The jigger-infected vessels as well as the clothing and bedding of their crew and passengers, who numbered 729, were disinfected. One of the vessels was reported to have had eight deaths from plague during the voyage, and on arrival another case was sent to the Modikhana Plague Hospital for treatment. Four vessels which were reported to have landed at Karáchi 74 cases of jigger and to have undergone the necessary disinfection there were not treated as infected arrivals at Bombay although they were subject to medical examination on arrival. Thirteen vessels with 6,466 pilgrims arrived from Jeddah, four of which had seven cases of small-pox. The vessels were thoroughly disinfected. It was compulsory to disinfect the clothing and bedding of the returning pilgrims before they were made over to the Protector of Pilgrims for despatch to their homes in India and beyond the Indian frontier. The remaining 10 vessels with a total crew and passengers of 1,994 persons had on board five cases of plague, two cases of cholera, two cases of small-pox, one case of measles and 16 cases of chicken-pox. The vessels and the kit of the persons among whom the cases occurred were disinfected.

The ship which had 9 cases of plague on board was the S.S. "Khalif" which arrived in the Bombay harbour on the morning of 14th March from Zanzibar via Marmagoa. Her crew (65 in number) and passengers (2 cabin and 1 deck) were examined for jigger, but no cases of jigger were found among them. The Commander of the vessel reported that 8 persons (including the 3rd Officer and a deck passenger) had died on board the vessel during the voyage, and had been buried at sea, and also that one of the crew was ill on board. This man (a coal-trimmer) had been ill for 14 days. On examination in the forehold where he was isolated he was found to be suffering from fever and a bubo in the left femoral region. He was removed to the Modikhana Plague Hospital, where he was diagnosed to be suffering from plague. From the history of the eight persons who suffered from fever and enlargement of glands, and who died during the voyage, there is not the least doubt that they all died of plague. The first patient (3rd Officer) was attacked on the 27th February, and died on the 4th March. He used to give out stores daily from the store-room to the native crew. These eight deaths all occurred between the 4th and 11th March. On 20th February about 50 dead rats in all were found in the store-room and forehold by the officers of the ship. The ship on arrival in Bombay on 14th March had the decks, forecastle and latrines thoroughly disinfected with a solution of carbolic acid. The store-room and holds were fumigated by burning sulphur in them at the rate of 6 lbs. per 1,000 cubic feet of space. At the Captain's wish the provisions in the store-room to which the rats had access were destroyed. As the plague on the S.S. "Khalif" appeared to be due to infected rats or cargo a short report on the case was submitted to Government with this Office letter, No. 964, of 2nd April, 1903.

The vessels which arrived from East African ports were inspected with a view to detect cases of sleeping sickness as per Government Resolution No. 2969, of 28th May, 1902. Up to the present no case of that disease has been discovered here.

Outgoing vessels.—The medical examination of the crew and passengers of all vessels and the disinfection of the clothing and bedding of the Asiatic and African members of the crew, who were not officers, engineers, doctors, or Japanese, and of the deck, 3rd and 4th class passengers and Asiatic and African servants bound for ports out of India were carried out immediately before they left the Port of Bombay as laid down in the Medical Inspection Rules published under Government Notification No. 3892-P., dated the 14th June, 1899, and Rule I issued under Government Notification No. 2671-P., dated the 2nd October, 1902. The inspection of the crew and passengers was done by day, on shore, in sheds specially arranged for that purpose. The disinfection was carried out at the disinfection station on the Frere Road, near the Prince's Dock, or by means of the stove on the floating disinfection barge.

During the year under report 14,463 outward bound vessels with 237,995 crew and 459,055 passengers were inspected. Thirty-nine cases of plague, 217 cases of small-pox, eight cases of measles, and 63 cases of chicken-pox were detected.

Of the 14,463 outgoing vessels 461 vessels with a crew of 43,974 persons and 40,624 passengers left for Aden, or ports in the Red Sea and Europe; 320 vessels with 28,664 crew and 26,486 passengers for ports out of India; and the remaining 13,682 vessels with 165,357 crew and 391,945 passengers for Indian Ports including Burma.

The clothing, bedding and boxes and other suspected articles of 45,708 Asiatic and African members of the crew and of 34,121 3rd and 4th class and deck passengers and pilgrims who sailed on steamers bound for ports out of India were disinfected. In addition to this disinfection, the kits of 3,950 crew and 508 passengers who sailed in native craft for ports out of India were also disinfected. Thus the total number of outward bound crew and passengers whose clothing, bedding, &c., was disinfected comes to 84,287 during the year under report against 79,338 during the year preceding.

The disinfection of the clothing and bedding of the crew and passengers of vessels which proceeded to ports out of India via Karáchi was not carried out at Bombay, *vide* Government Resolution, General Department (Plague), No. 1210-P., dated the 7th April, 1902, as the agents preferred to have the disinfection done at Karáchi.

An apparatus for the disinfection by means of formaldehyde gas of boots and shoes of crew and passengers of vessels was supplied by the Director-in-Chief, Plague Research Laboratory. The apparatus is capable of taking 72 pairs of country shoes at one charge and requires 25 minutes for "ordinary" disinfection and 90 minutes for "absolute" disinfection. It takes close on three hours for the "ordinary" disinfection and nine hours for the "absolute" disinfection of 350 pairs of boots and shoes of the native crew of a large ship. As it is difficult to give this much time to the disinfection of boots from one ship the purchase of another boot and shoe disinfector of an improved pattern and of at least double the capacity of the present one has been suggested to Government.

It was found by Professor Haffkine that plague microbes ceased to grow in an appropriate artificial medicine after having been subjected for 25 minutes to formaldehyde gas derived from five paraform tabloids, but that they had still vitality left to enable them to recover their primitive vigour when injected into the body of a rat. In order to efficiently devitalize the plague bacillus and render it incapable of growing in the body of a very susceptible animal, it was found necessary to increase the paraform tabloids to 60 and the time of exposure to one and a half hours.

The crew and passengers of five vessels which called at this port merely to land or embark passengers were exempt from inspection and disinfection in accordance with the proviso to Rule I of the Medical Inspection Rules. Such of the crew and passengers as embarked at Bombay on the vessels were inspected by day on shore; the new native crew and 3rd and 4th class and deck passengers had their effects disinfected.

The Agents, Commanders, and Nacodas of all outgoing vessels, including native sailing craft, with the exception of a very few, were careful in paying attention to the sanitary state of their ships, and in almost all cases they have cheerfully carried out the instructions and advice of the Port Health Officer. The forecastles were limewashed, painted or disinfected before departure. The bilges of native sailing craft were generally clean at the time of inspection. Those that were found to be dirty or to contain foul water had to postpone their departures until they were thoroughly cleaned.

Seventeen vessels had cases of infectious diseases among their crew and passengers within 10 days prior to their departure from this port. The Bills of Health granted to these vessels mentioned the illness which occurred on board, and the measures which had been taken before departure for the prevention of the spread of the disease. Six vessels were allowed to convey to Europe and the Persian Gulf coffins containing the remains of certain persons who were certified to have died of non-infectious disease. The persons interested had the permission of the Governments of their country to convey the corpses.

An enquiry was addressed to the Bombay shipping Agents as to whether any of their steamers which were in possession of the Bombay Bill of Health met with any vexatious delay owing to quarantine regulations at foreign ports. All the

Agents, with the exception of the Agent, Austrian Lloyd's Steam Navigation Company, the Agent, German East Africa Line, and the Agent, Bombay and Persia Steam Navigation Company, Limited, report that none of their steamers were delayed at other ports.

Infectious Diseases on Vessels in the Harbour and Docks.—During the year under report 32 vessels, including native sailing craft which were lying at different berths in the Victoria and Prince's Docks and at the various banders in the harbour, had on board 20 cases of plague, of whom 19 died, nine cases of small-pox, and three cases of measles. In addition to these cases two persons (dock labourers) were found dead at certain wharfs in the Prince's and Victoria Docks. The cause of death in these cases was attributed to plague. All these vessels and those mentioned in the third paragraph of this report, as well as the places where the coolies were found dead, were thoroughly disinfected in accordance with the Regulations issued under the Venice Sanitary Convention and the Indian Ports Act.

The following table includes all steamers, square-rigged vessels and native craft which became infected while lying in the Port of Bombay during the year 1903:—

Months.	Number of Persons who were attacked with Plague at Bandars and in the Docks.		Total Number of Cases of Infectious Diseases in the Bombay Harbour.															
			Total Number of infected Vessels.	Cholera.		Small-pox.		Measles.		Chicken-pox.		Plague.		Enteric Fever.		Scarlatina.

Port Observation Camp.—The area of land which was occupied by the camp was reduced on 1st June, 1903, from 12,555 square feet to 10,854 square feet, the monthly rent for which amounts to Rs. 75-15-8. This camp received some of the persons who were rejected, and sent there from the outward and inward inspections. They were kept under observation until their temperature fell to normal or until it was certain that the symptoms from which they suffered were not due to plague. Among the passengers and crew who were sent to the camp from the outward inspections, 39 developed plague and were transferred to the Modikhana Hospital for treatment. The sheds of the camp in which the plague cases developed were thoroughly disinfected with perchloride of mercury, and were kept unoccupied for some days. One hospital assistant and one ayah were employed to look after the inmates of the camp. The sweeping of the camp was done under arrangements made with the Public Health Department of the Bombay Municipality. The lime-washing of the sheds, floors, &c., and the general repairs to the camp were carried

out by the Executive Engineer, Bombay Presidency. One of the Senior Medical Officers was detailed in turn every fortnight to supervise the general working of the camp.

One of the sweepers in the Port Health Camp was sent to the Modikhana Hospital suffering from plague. He died in the hospital two days after admission.

Disinfection of Ships and Infected Cargo.—The total number of infected vessels of all sorts disinfected under the personal supervision of the Port Health Officer or of his staff was 55 during the year. In certain cases the disinfection barge was placed at the disposal of the Royal Navy and Royal Indian Marine Authorities for carrying out the disinfection of linen, mattresses and the clothing and bedding of the crew belonging to infected Naval and Indian Marine ships or transports on board of which were diseases which, although infectious, did not come under the infectious diseases mentioned in notification issued under the Indian Ports Act.

The vessel on which a case of cholera occurred had the drinking water on board discharged into the sea. The water tanks were thoroughly disinfected inside with potassium permanganate solution before they were refilled with a fresh supply of drinking water.

General Health of the Shipping.—During the year 867 persons connected with the shipping were admitted into the various hospitals in the city. The St. George's Hospital admitted 439 European patients, of whom 19 died, 404 discharged cured, and 19 remained after 1st January, 1904, under treatment. The Jamsetjee Jeejeebhoy Hospital admitted 142 Native patients, of whom 19 died, and the Goculdas Tejpal Hospital 286 Natives, of whom 25 died.

No deaths occurred from the effects of cleaning bilges of ships during the year. There were 235 accidents and 28 deaths due to accidents on board of ships which were lying in the harbour and docks. It appears that there is no Employers' Liability Act in India.

Red Sea Pilgrim Traffic.—Outward Pilgrim Traffic.—In the last year's report the number of pilgrims who sailed between the date, viz., 1st December, 1902, on which the camps at Pir Pao were opened, and the date, viz., 31st December, 1902, on which the year ended, was mentioned. The ships which sailed with pilgrims for Jeddah between 1st of January, 1903, and 6th February, 1903—the date on which the camps were closed—were as follows:—

S.S.	"Simla"	left with	391	pilgrims on	16th January,	1903.
,,	"Hooseinee"	,,	408	,,	20th ,,	
,,	"Haidari"	,,	501	,,	22nd ,,	
,,	"Kilwa"	,,	364	,,	29th ,,	
,,	"Gulf of Trinidad"	,,	552	,,	4th February,	1903.
,,	"Shahnoor"	,,	405	,,	6th ,,	
			2,621			

As a special report of the pilgrim traffic for the period extending from 17th October, 1903, to 30th January, 1904, has been forwarded to Government, it is considered not necessary to repeat in this report all the matters therein dealt with. During that period—17th October, 1903, to 30th January, 1904—16,401 pilgrims were segregated for 10 days in the camps specially erected for that purpose at Pir Pao, in accordance with Government Notification, No. 5282, dated the 7th October, 1903. This number does not include Her Highness the Begum of Bhopal and party comprising 305 persons who left in the S.S. "Akbar" on 30th October, as they were not segregated in Bombay. They had been segregated at Bhopal. During segregation 17 pilgrims died in the camp hospitals. The death-rate among so large a number of pilgrims while undergoing segregation is very low, more especially when it is taken into account that many of them were old and feeble.

Between 17th October, 1903, the date on which the camps were opened, and 31st December, 1903, the date for which this report is prepared, 13 vessels left for Jeddah with 8,300 pilgrims, and between 1st January to 30th January, 1904, 11 vessels left for Jeddah with 8,347 pilgrims. The number of vessels and the number of pilgrims which they conveyed to Jeddah during the pilgrim season of 1903-04 is 24 and 16,647, respectively.

During the pilgrim season many Mahomedans left for Aden as "shopkeepers" and for Suez as "travellers" and "merchants." The most of these people were undoubtedly pilgrims, and the Venice Convention lays down that pilgrims shall be segregated before being allowed to leave an infected country. Shipowners complained that they were not able to get many saloon pilgrims for their ships, as many of the Mahomedans who left for Aden and Suez were well-to-do passengers and would, if they had undergone segregation, go as saloon passengers by the pilgrim ships.

During the pilgrim season and while Mahomedan passengers were leaving by ordinary ships for Aden and Suez, the agents of a certain ship stated that they intended to take from Bombay without segregation 300 Mahomedan passengers for Suez, as that port does not come under the Pilgrim Ships Act, *vide* Notification (2), Section 5 of the Act. However, the idea was not carried out.

Inward Pilgrim Traffic.—Thirteen vessels brought to Bombay 6,466 pilgrims from Mecca viâ Aden and other routes. Four pilgrim ships arrived in Bombay with seven cases of small-pox. The baggage of these returning pilgrims was disinfected at the disinfection shed near the Prince's Dock. Pilgrims whose homes were up-country or beyond the frontier were not allowed to enter the town. They were made over to the Protector of Pilgrims for despatch direct from the disinfection shed to their homes by rail.

Sanitary State of the Harbour and Foreshore.—The sanitary state of the harbour and of the various bandars, basins and docks has been fairly satisfactory.

Cholera, Small-pox, and Plague in the City of Bombay.—During the year 17 deaths from cholera, 1,477 deaths from small-pox, and 20,788 deaths from plague occurred in the City of Bombay against 75 deaths from cholera, 288 deaths from small-pox, and 13,820 deaths from plague during the year preceding. The city was free from cholera in an epidemic form during the year. There was a heavy mortality from small-pox in February, March, April, and May. Plague raged as a virulent epidemic from January to May inclusive.

Whenever plague developed among the crew or passengers who were not allowed to sail on a vessel for ports out of India, Government were informed of the fact in order that the authorities at the vessel's next port of call may be made acquainted of the occurrence by wire. When a plague case occurred among those who were prevented from sailing on vessels bound for Indian ports, the Port Health Officer communicated the fact to the authorities at the next port at which the vessel was intended to touch.

There is a Clayton's apparatus in this port for the disinfection of ships' holds and for the destruction of rats and cockroaches on board vessels by means of sulphur dioxide. The apparatus belongs to one of the shipping firms in Bombay and is used by them in the disinfection of their steamers when necessary.

ABSTRACT OF THE REPORT OF THE CALCUTTA MUNICIPALITY FOR 1903-1904.

(*R. T. Greer, Esq., Chairman.*)

Suburban Sewerage Scheme.—Substantial progress has been made in the execution of this scheme which is estimated to cost £460,000. The work is divided into 14 contracts, two of which have been completed, while in the remainder work is in progress. In October, 1903, the work upon Main Sewer No. 1, which had been interrupted in 1900, was resumed under a new contract, and it is now nearly completed, the portions previously constructed having been examined and cleansed. This sewer passes through Kidderpore and Alipore, and only two short lengths adjoining Tolly's Nullah remain to be done. Great difficulty has been experienced by the contractors in the construction of a syphon under the Nullah, and these have not yet been overcome. Four miles out of the 22½ miles of sewers included in Mains Nos. 1, 2, 4 and 5 have been completed, and the progress made is satisfactory. The storm-water outfall works have been completed with the exception of a portion of the reservoir and the Makalpotta Sluice. The new town high-level sewer to have a 30-foot roadway over it; the new storm-water outfall for the suburban system of sewers, and a combined sewage channel for both the city and suburban sewers have been completed with the necessary sluices, bridges, syphons, &c. The suburban high-level sewer has been completed during the year, and the reflux gates in the suburban head-cut, the extension of the combined sewage channel, and new pumping stations at Ballygunge and at Budge-Budge Road are under construction. The scheme for the surface drainage of the suburbs is under preparation.

The design for the Balliaghatta drainage is complete and the sanction of Government has been obtained; the work will probably be taken in hand during the current year.

Water-supply.—The total quantity of filtered water supplied to the town, added area and suburbs during the past year amounted to 7,624 million gallons as compared with 7,542 million gallons during the previous year. If the population supplied with filtered water in Calcutta and the suburbs is estimated at 960,000 the supply per head of population would amount to 21·5 gallons. A mile was added to the filtered water mains, and the mileage now stands at 185 in the town and 133 in the added area, making a total of 318 miles.

The conversion of the intermittent to a constant supply has been hampered by the insufficient quantity of water which reaches Calcutta, but the population supplied under the constant system now totals 210,898, and was nearly doubled during the year. The average rate of consumption per head in the area under constant supply fell from 31·4 to 24·1, and much of this reduction was due to the work done in repairing leaky mains and connections, to surcharges for excess consumption, and to prosecutions for waste. An additional Assistant Engineer, Mr. H. J. Trivess Smith, was brought out from England in October last to push on with the work of conversion. The further extension is, however, at present in abeyance pending an increase in the water-supply, the urgent need of which has long been felt. Since the close of the year, the Corporation have sanctioned a scheme for augmenting the supply by putting pressure on the mains at Pulta.

A new proposal has been put forward by the Chief Engineer for the substitution of an elevated reservoir at Tallah for the existing system of pumping stations, his object being to supply the town and suburbs with water by gravitation instead of by pumping. This scheme is under consideration by a special committee.

The total quantity of unfiltered water supplied during the year amounted to 6,529 million gallons, which means an average of 24·1 gallons per head per day for

the 740,000 people supplied. The unfiltered water supply has been extended into 359 sewered roads, 40 miles having been added to the system of pipes, the total length of which now exceeds 212 miles.

The expenditure on water works amounted to £111,750 and the receipts to £107,100. The total fees realised by the sale of water to the shipping amounted during the year to £4,468, which is slightly below the receipts for the previous year.

Bustee Improvement.—This department is in charge of the Deputy Chairman. Improvements have been effected in two bustees under Sections 400 to 405, and in four other cases the owners voluntarily came forward with plans for new bustees. Much useful work has been done under Sections 406 and 407, though delay has resulted from the necessity of recommencing proceedings *ab initio* in several cases in which the original plans had not been approved within six months. The General Committee called for fresh reports in the case of 24 bustees and for new reports in the case of 18 others, and the services of the Plague Officers were utilised in preparing schemes.

Standard plans have now been approved for 24 bustees (7 in District No. I., 4 in District No. II., 9 in District No. III., and 4 in District No. IV.) and the subsequent action taken has resulted in the clearing away of the bustee at 6-3, Hiralal Mitter's Lane (District No. I.), and the whole of the bustee area (in District No. III.) of 25, Park Street and 1 and 2, Rawdon Street. At 133-134, Corporation Street masonry buildings are in course of erection on part of the old bustee, and the remainder is being improved in accordance with the directions of the Committee. The owners of 65-68, Machua Bazar Street, 47, Sham Bazar Street, 54-55, Sukea's Street (District No. I.) and of 17, Kassinath Mullick's Lane (District No. II.) have undertaken to carry out improvements, and the Corporation will be asked to contribute by making roads. Much work of a preliminary nature has also been done which will bear fruit later. Other improvements include the clearance of part of 23, Chatawalla Gully under the Plague Regulation, the acquisition and clearance by the Corporation of the most insanitary part of Jorabagan Bustee (in Ward V.), a noted plague centre, for the purposes of a public square, the improvement of Goomghur Bustee, through which the Corporation have constructed a wide thoroughfare, and the acquisition of the bustee at 26-27, Free School Street, purchased with a view to improving the eastern approaches of the Sir Stuart Hogg Market. The bustees at 28-30, Banstalla Gully, at 97 and 104-107, Ahiritolla Street, at 58, Upper Chitpur Road, and a portion of Tantibagan Bustee have also been rebuilt. The population dislodged from these demolished bustees is moving eastwards and southwards, and special action is being taken to lay out areas in advance for their occupation. An area of over 2,200 biggahs of land has already been laid out, spaces having been provided for roads of sufficient width at regular intervals. A scheme is under consideration for the construction of model dwellings on land belonging to the Corporation at Haritola.

Plague.—The plague mortality shows a substantial decline as compared with the statistics of recent years; the seasonal development has been somewhat later than usual. As in former years, the north of the town (comprising Wards 1-12) has been by far the worst affected. A special feature of the year's preventive work has been the demolition of large numbers of the most infected huts in bustees which have been ravaged year after year by the disease. It is too early yet to express a final opinion upon the success of this measure, but the consistent decrease in the mortality affords ground for hopeful anticipations. No steps have yet been taken to provide accommodation for the dislodged population, whose numbers are further swollen by the wholesale private purchase of bustees in the south of the town, which are being replaced by masonry structures. Disinfection has been carried out on a large scale, and arrangements were made to inoculate all willing to be inoculated. A list of precautions against the spread of plague was drawn up in simple language and printed in the vernacular, and freely distributed in all parts of the town.

The Plague Department continues to be administered by the Chairman under the authority vested in him by the Plague Regulation, expenditure being met from the revenue funds of the Corporation, with the exception of a small sum which represents the balance of the Plague Loans.

Health Department.—The death-rate was 35·1 per 1,000 as against 37 in the preceding year; the rate, excluding plague deaths, being 25·4 per 1,000. Cholera accounted for close on 2,000 deaths, but this was below the average, in spite of the fact that the mortality from this disease for this year was above the average in the province, and was specially severe in the district of the 24-Parganas. Several cases in the south of the town were traced to the use of the filthy water of Tolly's Nullah by pilgrims. Insanitary wells and tanks are still numerous, and it is a satisfactory feature of the year's work that 47 wells and 56 tanks were filled up. The mortality from malarial fever has diminished, but tuberculosis has increased in the last few years. The Health Officer's proposal to establish a sanatorium for the treatment of advanced cases of the latter disease was disapproved by a Sub-Committee on the ground that the social life and customs of the people would render the scheme ineffective.

The birth-rate registered rose from 14·2 to 15·5 per 1,000, but even the latter figure is far below the actual facts. The experiment of appointing a staff of peripatetic sub-registrars to collect information of births proved very successful, the number of births registered in the area under experiment being 51 per cent. above the average of the past three years, and it is proposed to extend the system to the other three districts.

Vaccination returns showed a further decline, and the department was again remodelled towards the end of the year by the appointment of seven inspectors and 24 vaccinators, the former on Rs. 60 to 75, and the latter on Rs. 20 to 30. The change yielded improved results during the last quarter of the year. Vaccine was obtained from Madras, pending the completion of the new vaccine depôt at Ballygunge. The outturn of work of the sanitary inspectors has been somewhat less than last year; their prosecutions resulted in the imposition of fines amounting to £2,058. The food inspectors did useful work and destroyed large quantities of unwholesome food, special attention being devoted to the milk, fish, mustard oil and ghee supply.

Much useful work has been done at the Municipal Laboratory. The filtered water-supply has been subjected to weekly analysis, and it maintained its character as a wholesome water, the only unsatisfactory feature being the continued presence of bacteria of the *colon* group. A large number of samples of food-stuffs were analysed. The gas was also regularly tested with satisfactory results, and bacteriological work was done both for the Plague Department and for private medical practitioners.

Cemeteries, Burial-grounds, &c.—Six insanitary burial-grounds were closed during the year, including the old Durgapore burial-ground, which had been the subject of much litigation in the Alipore Courts. The land recently acquired for Mahomedan burial grounds at Gobra and Bagmari has been taken over and prepared at a considerable cost. The land acquired in the previous year for an extension of the Lower Circular Road Christian Cemetery was, during the year under review, properly prepared and enclosed and handed over to the Christian Burial Board. An expenditure of £2,114 was sanctioned for raising the level of part of the area which has been taken up for a new Christian cemetery at Jadabpore; the work is in progress. Tenders for the construction of a crematorium of the latest improved design have been invited.

Conservancy.—The supervision of conservancy forms part of the duties of the District Engineers under the Reorganisation Scheme of two years ago, but the advisability of creating a separate department to take charge of this important work has been for some time under consideration. Upon the recommendation of a Special Committee, the Corporation decided in favour of the creation of a separate department (to be styled the Cleansing Department), under a responsible head, who should work directly under the orders of the chairman; but the Corporation postponed the consideration of the details of the scheme, and have not yet sanctioned the creation of the post of head of the new department. They have negatived two proposals on the subject, and the execution of the scheme is therefore still in abeyance. In the European wards the conservancy arrangements are, on the whole, satisfactory, and there has been some improvement, but in the north of the town the need for an afternoon service is keenly felt, and in the suburbs the establishments are undermanned. In December last the Commissioners sanctioned a special expenditure of

£1,400 for the maintenance of additional establishments in the northern wards of the town, for special conservancy and cleansing of bustees, as a precautionary measure against plague.

The experimental incinerator which Messrs. Joseph Baker and Sons, of London, have contracted to set up, under a guarantee against nuisance, at Entally, was completed before the close of the year, but the preliminary tests made rendered certain minor structural alterations necessary, and the incinerator has not yet been made over to the Corporation to work. When this is done, the contractors will be required to work the plant for eight months, including the rainy months, and an official trial will then be conducted.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR 1903.

(*Dr. J. Nield Cook.*)

Births.—The birth-rate of the town calculated on the registered birth was 15·5 per 1,000 of the population. As I have estimated in my last annual report that the true birth-rate of Calcutta should be not less than 26 per 1,000, basing my calculation on the number of women of child-bearing age living in Calcutta and the general fertility of women in this country, it is evident that the registration of births is still very defective.

I mentioned in my last report that the Commissioners had sanctioned a trial of a new system of registration of births in one district for one year as an experiment. Dr. Sen has carried it out in District I. One Registrar was employed to register births at the District Office and eight Sub-Registrars to conduct inquiries in the wards and obtain information of any births that occurred. A warning notice was issued to the parents of each infant, and if they failed to register the birth after that they were prosecuted. The results are encouraging, for in the nine months from April to December, the number of births registered in this district was 51 per cent. more than the average of the corresponding periods of the three preceding years in this district. I consider that this result is creditable to Dr. Sen, who carried out the experiment, and points to the desirability of adopting the system in the remaining districts. The number of still-births for the year was 6·6 of the total births, including the still-born.

Deaths.—The death-rate of the town was 35·1. A recrudescence of plague, which was somewhat severe, was the cause of this high figure. If the deaths reported under this head be subtracted from the total, the death-rate is reduced to 25·4, which is quite a moderate rate for Calcutta. Plague was administered by a special department, independent of the Health Department. It accounted for rather more deaths than the previous year. There was a good deal of cholera in the town in the first half of the year, though the total mortality from this cause was somewhat below the average. This may be considered fairly satisfactory, as the cholera mortality was above the average in the province and specially severe in the 24-Pergannahs which adjoins Calcutta on three sides. Still, taking into consideration the fact that Calcutta has a filtered supply of drinking water which has never been found to contain the germs of this disease, though it has been specially examined for them every week, there ought not to be nearly 2,000 deaths from cholera in a year. There is very little that can be done to check it, as it is in a large measure due to importation by pilgrims from outside, and in the town, as Dr. Mullan, the District Health Officer, has recently collected a number of cases to show, from the use of the water of Tolly's nullah in connection with the pujahs of Kalighat Temple. The water of the nullah is very impure and has often been found to contain cholera germs. The obvious measures are the improvement of the nullah by diverting drainage when the suburban sewerage is completed and patrolling the banks in the early morning to prevent the commission of nuisance. The devotees who bathe in the water and drink it will continue to do so until the gradual spread of education convinces them that they can serve their gods equally well without risking their lives by drinking diluted sewage. The polluted tanks and wells in the towns are also an important cause of the disease and a number are filled up every year under notices and prosecutions by the Health Department. The mortality from small-pox was low, as there is a more or less marked cycle in Calcutta extending over about five years, and we are at present in the period of

comparative quiescence. The mortality from fever was comparatively low, though it was somewhat above the average in the province and in the division of the 24-Pergannahs.

The comparatively low mortality registered as fever, 4,869 against 8,036 deaths, is to some extent to be attributed to more deaths being registered under "Other Causes," but, apart from this, I believe that there has been an appreciable diminution in malarial fever in Calcutta in the last few years. Fifty-one deaths were registered under enteric, which is probably below the actual number, as enteric in the native is apt to pass unrecognised and to be confused with other febrile complaints, and it is quite exceptional for medical practitioners in the town to notify their cases. In my last report I wrote at some length on the prevalence of phthisis in Calcutta. The mortality from this cause again shows an increase, amounting to 1,580, or 7·3 per cent. of the total mortality exclusive of plague, which I believe to be below the actual mortality from this cause. The question of adopting measures for dealing with this disease was considered by a Sub-Committee of the Commissioners, which was altogether opposed to my proposal to establish a home for advanced cases and made so much of the difficulties in the social life and customs of the people that I thought it advisable to await the growth of public opinion before commencing the campaign.

Vaccination.—The vaccination returns again show a falling-off on the whole, though there was a slight increase in Districts I. and III. Vaccination was performed during the greater part of the year by Hospital Assistants under the supervision of the District Health Officers, but without any Inspectors. I expressed my opinion in my last annual report that this system did not work well, and the question of the reorganisation of the Department was considered by the Commissioners, first by a Medical Sub-Committee and subsequently by the General Committee and Corporation, and the follwing recommendations were passed and confirmed:—

I. That the Health Officer and District Health Officers be called Superintendent and Deputy Superintendents of Vaccination, respectively.

II. That seven Vaccination Inspectors be appointed, two each for Districts I., II. and IV. and one for District III. on Rs. 60 rising to Rs. 75 in ten years by equal biennial increments.

III. That twenty-four Vaccinators, to be selected by the Health Officer, on Rs. 20 rising to Rs. 30 in ten years by equal biennial increments, be appointed.

IV. That the Female Vaccinators be employed in addition as at present.

This came into force on the 1st November, though some of the Hospital Assistant Vaccinators were kept on for the time being. It is too soon to report on the result of the change, but in the last quarter of 1903 the number of vaccinations was 4,264 against 3,668 in the corresponding quarter of 1902, which is encouraging.

I reported a year ago that a site had been purchased, plans passed and tenders accepted for the construction of a depôt for animal vaccination and the manufacture of preserved vaccine in Ballygunge. Owing to the land having to be raised and tedious delays having occurred in consequence, the new depôt has not yet been built. The preparation of vaccine was carried on under difficulties for the greater part of the year owing to insufficient accommodation for the calves and repeated outbreaks of rinderpest, which made it difficult to keep up a good stock, but eventually I obtained permission to discontinue the preparation of vaccine until the new depôt was completed and to purchase sufficient glycerised vaccine for my requirements from the Madras Municipality, which has been done with good results. The vaccination returns show that glycerised vaccine compared favourably with lanoline paste and calf lymph, and when the new depôt is opened I propose to give up lanoline altogether in favour of glycerine and to do most of the vaccination with glycerised vaccine if the people do not object and so avoid the inconvenience of carting about calves for vaccination.

Filtered Water-supply.—Fifty-two samples of Hugli River water as pumped into the settling tanks at Pulta, 52 samples of water from the settling tanks, and 104 samples of filtered water from the town supply were examined during the year. In the filtered water, the total solids, chlorine as dissolved chlorides, and total hardness ranged high from January to June, varying from 19 to 27 parts, 0·9 to

2·7 parts and 7·5 to 14 parts per 100,000, respectfully; while from July to December all these constituents diminished, ranging from 8·5 to 18·5 parts, 0·4 to 1·2 parts, 4·75 to 8 parts per 100,000, respectively. The albuminoid ammonia as determined by Wanklyn's process, the nitrates and the oxygen consumed varied from 0·0032 to 0·0056 part, 0·016 to 0·026 part, and from 0·004 to 0·012 part, respectively, during the year.

The water was free throughout the year from "free ammonia" and "nitrates." A slight opalescence in the filtered water was noticed during the rains, which is a recurring feature every year. Thus chemically considered, the filtered water supply of Calcutta maintained its character as a wholesome water.

Special bacteriological examinations of the filtered water were made every week throughout the year and in all the examinations the samples were found free from B. Typho-Abdominalis, B. Enteritidis sporogenes and Comma Bacilli.

The only unsatisfactory feature is the continued presence of bacteria of the Colon group, which were found in every examination of the filtered water in relatively large numbers. Bacterial counts of the filtered water as supplied to the town as well as those of the water from the collecting wells of the 36 filter beds at Pulta were generally below 100 per 1 c.c. The enumerations show no constant and definite relation between the head of water, number of days the filters have been in use and the number of bacteria found in the water.

Other Laboratory work.—Two hundred and forty-five samples of water from the River Hugli, settling tanks, filtered water of the town and from local tanks were examined. In 7 samples of tank water comma bacilli were found. It may be noted that in every instance cases of cholera occurred in the vicinity of such tanks. Eleven specimens of blood were tested for enteric fever by Widal's reaction and in five a positive result was obtained. Out of four specimens of sputum examined one showed tubercle bacilli. Two specimens of exudation from the throat were examined and in one diphtheria bacilli were found. Thirty dead rats and one guinea-pig were sent near the end of the year by the District Medical Officers of the Plague Department in connection with the occurrence of suspected plague cases in different parts of the town and examined, but plague bacilli were not found in any of them. It may be mentioned, however, that rat plague recommenced early in 1904. Samples of filth from the North Gowkhana were examined bacteriologically, and bacilli of malignant œdema, tetanus and cholera were found.

Out of 184 samples of ghee, 148 of milk, 8 of butter, 30 of barley powder, 6 of flour, 8 of arrowroot, 64 samples mustard-oil and 7 of a miscellaneous character analysed, 53 of ghee, 107 of milk, 1 of butter, 24 of barley powder and 42 of mustard-oil were found to be adulterated. The Analyst attended Court on 34 occasions to give evidence in adulteration cases.

Work done by the Sanitary Inspectors.—There were 4,602 notices served for the abatement of nuisance and 3,310 prosecutions with an aggregate fine of £1,255. There were 1,772 prosecutions in licence cases with an aggregate fine of £800. The number of cases of disease investigated was 8,617. The number of houses disinfected was 1,985 and steps were taken to remedy the sanitary defects found in the premises. Bedding and articles of clothing were disinfected and useless articles were burnt.

During the year all cases of death other than plague were enquired into and reported on by the Sanitary Inspectors. This has rendered the causes of death in the returns somewhat more accurate.

Most of the prosecutions in licence cases were, as in the previous year, due not to the owners being unwilling to take out licences, but to their carrying on their trades in insanitary premises for which licences had been refused until such time as the places should have been put in a sanitary state.

Fifty-six tanks and 47 wells were filled up during the year.

ABSTRACT OF THE REPORT OF THE MADRAS MUNICIPALITY FOR 1903-04.

(*S. D. Pears, Esq., President.*)

New Drainage Works.—In the early part of the year, the preparation of the detailed estimates for the whole scheme was completed, and the total abstract thereof was revised. The total estimate, thus revised, for the scheme, amounting to £324,364, was sanctioned by the Commissioners on the 29th May, 1903. The laying down of the cast-iron main was in progress, and 388 lineal feet of piping were laid, raising the total length laid to 11,319 feet. In fact, the whole length except the bit near the Mylapore Pumping Station, about 400 feet long, is completed. The flooring of the engine and boiler-house on Ice House Road was completed after the fitting up of the machinery.

At Napier Park, the Worthington pumps and boilers were procured, fitted up and tested. The connections to the cast-iron main from the two pumping stations above specified—Ice House Road and Napier Park—were laid up to the proposed stand-pipes.

The laying of sewers in south Triplicane was resumed, and 28,859 feet of pipes were laid.

The draining of Kosapet, Mylapore, was also put in hand and completed.

In addition to the above several other drains were completed during the year.

Water Supply.—During the year under report 948 yards of new pipes were laid and 10 fountains, 1 valve, 18 stop-cocks, 16 hydrants and 22 meters were fixed. The total length of pipes taken up, cleaned, and relaid during the year was 15,123 feet; this brings the total length taken up, cleaned and relaid since the commencement of the operations in September, 1900, to 337,291 feet.

On the 1st of April, 1903, the level of the Red Hills Lake stood at 42·85, and on the 31st March, 1904, at 43·22. There was no pumping during the year; the lowest level, 41·22, was reached on 26th November, 1903. The quantity of water supplied to the city during 1903-04 was 608,999,175 cubic feet, against 594,668,979 cubic feet last year.

Private Services.—Five hundred and thirty-three new services were laid by licensed plumbers during the year and 2,073 existing services were extended.

The quantity of water used for non-domestic purposes during the year was 105,690,667 gallons.

Vaccination.—The total number of cases vaccinated during the official year 1903-04 was 30,062, against 32,309 in 1902-03, showing a decrease of 2,247 cases, due to the less number of convicts vaccinated in the Penitentiary (372 less), coolies vaccinated in the Emigration Depôts (1,761 less), and cases vaccinated in the Municipal Depôts (114 less), as compared with the preceding year.

Out of the total cases vaccinated, 24,726 vaccinations were performed in the Municipal Vaccine Depôts and 5,336 in the Natal and Mauritius Emigration Depôts, as well as in the Penitentiary. In the Penitentiary, vaccination was carried on by the Municipal Vaccinator during the first four months of the official year and by the Medical Subordinates of the Penitentiary during the next eight months. 17,814 of the total cases were males and 12,248 females. The results of the vaccinations performed show that 26,453 were successful, 2,023 unsuccessful and 1,586 unknown.

The percentage of success obtained both in primary and re-vaccination excluding the unknown cases from the total was 92·90 against 90·34 in 1902-3, showing an increase of 2·56 per cent.

The different kinds of lymph employed in vaccination during the year are given below with the percentage of success obtained in each:—

—	Primary Vaccination.	Percentage of Success.	Re-Vaccination.	Percentage of Success.	Grand Total.	Percentage of Success.
Calf-to-arm vaccination... ..	17,249	99·84	2,337	83·57	19,586	93·00
Glycerine lymph	5,099	99·35	1,699	74·42	6,798	93·68
Lanoline vaccine	274	100·00	3,404	56·34	3,678	59·95

The lanoline paste obtained from the Mysore Vaccine Institute and used in the Emigration Depôts by the vaccinator employed by the Emigration Authorities in vaccinating the emigrant coolies (who were in most cases re-vaccinated) gave a percentage of 59·95 of success against 67·19 in 1902-3, showing a decrease of 7·23 per cent. The glycerinated lymph gave as good results as calf-to-arm vaccination.

The number of children vaccinated under one year was 17,036, including 31 cases which were done in the Emigration Depôts, against 15,092 in 1902-3, showing an increase of 1,944 cases due to the higher birth-rate in the previous year. Of the total, five were secondary vaccinations. The percentage of success obtained in the infant vaccination was 99·77 against 98·91 in the previous year. Of the total number of children vaccinated 13,006 were born in Madras and 4,030 in mofussil.

During the official year small-pox was far less prevalent than in 1902-3. There were only four deaths from this disease: one in April, two in May, and one in June, 1903. The infected houses were promptly disinfected by the sanitary staff. Every effort was made to induce the relatives of the small-pox patients to remove the infected cases from houses in which accommodation was insufficient to the Isolation Hospitals, and the infected houses were visited by the vaccine staff to vaccinate the unprotected children found in the neighbourhood. Re-vaccination was also encouraged in the infected localities and those who were willing to undergo the operation were re-vaccinated.

VITAL STATISTICS.—*Births.*—The total number of births registered during the calendar year 1903 was 19,830, exclusive of still-births, showing an increase of 2,087 births over the previous year. The ratio of birth per 1,000 of population was 38·9 against 34·8 of the previous year, the average of the ratios for the preceding decade being 40·1. This is the second highest number of births ever recorded in the City, the first being in the year 1900, which returned an exceptionally high number, 20,672. The greater number of births during the year under report occurred as usual in the second half of the year. Of the 19,830, the male live-births numbered 10,129 and the females 9,701, with the proportion of 104·4 males to every 100 females.

Deaths.—During the calendar year 1903 the total number of deaths registered from all causes was 19,205 against 21,395 in the previous year, the decennial average being 19,329·2. The ratio of death for the year was 37·7 against 42·0 of the previous year, the average of the ratios for the past decade being 41·4. In 1902 the number of deaths was greater than the births by 3,652, but in 1903 the number of births was greater than the deaths by 625. The year under report was on the whole a comparatively healthy one. Of the 19,205 deaths 9,874 were males and 9,331 were females, showing a proportion of 105·8 males to 100 females.

Mortality according to Divisions and Wards.—The 1st Division returned the highest death-rate, the ratio being 42·2, and the 4th Division returned the lowest with a ratio of 33·2. Amongst the 20 wards of the city, the 1st Centre, and the 2nd South, returned the highest death ratios, equally, viz., 47·5, while the 5th Division, South Ward, returned the lowest, 30·7.

Once again the death-rate of the 1st Division, Centre Ward, shows the extremely insanitary condition of this part of the city. So far as the portion of this ward known as Rope godown parcherry is concerned, it remains in the same primitive condition sanitarily as it was when the parcherry was founded, with the addition

that it is now probably a good deal more crowded and that the site has become progressively more polluted. As regards the Tinnevelly Settlement, a number of improvements was accomplished during the year both by the municipality and by private individuals, but until the whole place has been satisfactorily laid out, drained and provided with a good and constant water supply, and until the numerous insanitary wells have been closed and a larger number of suitable latrines have been provided, not much improvement in its mortality rate need be hoped for. The material condition of the inhabitants of 1st Centre, is, however, improving, judging by the large number of new buildings springing up on the sites of old houses. It is particularly necessary that the plans of these buildings should be carefully scrutinised and when passed that the actual building should be in accordance with or not inferior to the plan as regards its hygienic details.

The 1st Division, Centre Ward, continues to be the great rice-preparing emporium for the city, and it seems extraordinary that the chief food supply of the citizens should pass through the most insanitary corner of the town on its way to the consumer. If there is one portion of the town which ought to be scrupulously clean in every way and provided with the very best supply of water, it is this. The time is, however, approaching when the subject of its improvement will be taken up in earnest, and with the assistance of the Sanitary Commissioner, who inspected the Tinnevelly Settlement during the year, a scheme will, it is hoped, shortly be prepared for its improvement.

The high mortality in the 2nd Division, South Ward, is intimately connected with overcrowding and the existence in this ward of the extremely insanitary cattle yard area of Yedapalium. This latter evil could be remedied by the provision of a Municipal cattle yard on a plot between Wall Tax Road and the Canal immediately opposite to Yedapalium Street.

In most of the cattle yards in 2nd Division, South Ward, the cattle and the owner's family and probably some tenants dwell together in a house, barely more than sufficient for a fairly large family, so that neither the cattle nor the human beings have a fair chance. With a fairly large Municipal cattle yard at a convenient place it would be possible to close all the cattle yards of Yedapalium, and the sooner this is done the better.

Mortality according to causes:—During the calendar year the deaths have perceptibly decreased under all the principal heads of diseases. Five deaths occurred from plague (imported) against 10 in the previous year; 28 deaths from cholera (sporadic) against 37; 7 deaths from small-pox against 69; 96 deaths from measles against 225; 2,286 deaths from dysentery against 2,789; and 380 deaths from diarrhœa against 572.

Cholera.—Even with an improved water supply and satisfactory drainage over the whole city, it is impossible to hope that epidemic cholera will ever disappear from Madras while the state of the surrounding district remains as it is. Cholera is probably never absent from some part of the Chingleput district, and in nearly all cases in Madras last year the infection could be traced to a village outside, more especially to Saidapet, where the disease occurred amongst the dhobies. The infection there was traced to the river, the water of which was used by many for domestic purposes for want of a convenient supply of good water. The provision of a good water supply to the villages of the Chingleput district is almost of as much importance to Madras so far as protection from cholera is concerned as the provision of a good water supply for the city itself. Properly constructed and protected wells with pumps ought to be provided in every village.

Fevers.—During the year under report the total number of deaths from fevers was 6,129 against 7,326 in the previous year, with a ratio of 12·0 against 14·3. The average of the decade was 7,172·5. The 1st Centre Ward, returned the highest number of deaths from this disease, and the 6th North, the lowest, the former returning 731 deaths and the latter 53.

Infantile Mortality.—The number of deaths among infants under one year of age was 5,618 against 5,393 in the previous year, and the ratio calculated on the total infantile population under one year of age was 411·6 against 395·1, but the death ratio per 1,000 infants born alive was 283·3 against 303·9 of the previous year.

Plague Measures.—During the official year the Superintendent of Passports continued to supervise the passport establishment in the city. The plague staff remained the same as last year, except that an assistant passport examiner was added to each of the 3rd and 5th Divisions to cope with the work caused by the increase in the number of passports, and that the assistant plague inspector, 7th Division, whose services were dispensed with for some time, was re-entertained. For the Park Fair, the Industrial and Arts Exhibition and the Indian National Congress a special staff of eight plague inspectors was entertained.

Perambore and Bitragunta continued to be Passport Issuing Stations during the year.

The number of persons detained during the year in the two plague camps in the city was: Perambur, 1,370; and Egmore Plague Hospital, 99.

Nine imported cases of plague occurred in the city during the year, of which eight proved fatal. All of them were removed and treated in the Egmore Plague Hospital.

The total number of passports issued at Perambur during the year was 114,542 against 68,471 in the previous year, an unusually large number. This is due to a large increase in the number of notified stations and to the Indian National Congress and Industrial and Arts Exhibition. 3,127 passports were left untraced during the year against 1,065 in the preceding year, giving a percentage of 2·73 against 1·65. The number of mofussil passports received was 12,144 against 11,017 of the previous year. Of these 398 could not be traced, giving a percentage of 3·27 against 4·64 of last year.

The attendance of the passport holders was satisfactory. During the year there were 246 prosecutions and 151 convictions against 164 and 112 respectively in the previous year. The fines imposed amounted to Rs. 857-8-0 against Rs. 386 in the preceding year.

It is satisfactory to note that a very considerable amount of assistance in connection with the detection of actual or suspected cases of plague was received from the public during the year.

The Port Health Officer reports as follows with regard to the inspection of vessels:—314 vessels, departures from Madras, carrying a crew of 30,078 persons and 34,264 passengers, were inspected during the official year and granted bills of health. The inspection of the crews and passengers was carried out on shore. Besides the above, 161 vessels, arrivals from plague-infected ports, and carrying a crew of 13,323 men and 6,657 passengers for Madras, were inspected on board before communication between the vessels and the shore was permitted. All passengers landing at this port were granted plague passports. On board these 161 vessels 10,700 shore coolies worked. Before being sent on board the names and addresses of the coolies were taken down, and on their return in the evening they were given a disinfecting bath of perchloride of mercury—such of the coolies as were absent on the following morning were inspected at their houses under the orders of the Municipal Health Officer.

ABSTRACT OF THE REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR 1903-04.

(*W. L. Harvey, Esq., C.I.E.*)

PUBLIC WORKS.—*Drainage.*—The machinery at the Colaba Air Compressor Station and the several Ejector Stations and at the Love Grove Air Compressor Station worked satisfactorily during the year, except that at the latter station an accident occurred on the 20th June, 1903, which involved serious damage to No. 3 compressor engine.

The engines and pumps at the Love Grove Pumping Station also worked satisfactorily, except on one occasion when there was a total stoppage of a short duration caused by the fracture of a pump gland of No. 4 engine on the 11th December, 1903, at a time when No. 4 engine was the only engine at work.

The street portions of house drainage connections carried out numbered 711, at at cost of £1,848.

Latrines and urinals at different places have been constructed to meet the public convenience.

Works in connection with the sanitary arrangements of the various Health Camps, Observation Camps and Plague Hospitals were carried out by the Drainage Department, Ordinary Branch.

Several works executed by the Drainage Department, Special and Ordinary Branches, have been detailed in the Executive Engineer's report.

WATER WORKS.—*Tansa Lake.*—The rainfall for 1903 was 103·12 inches against 89·87 inches for 1902. The total quantity of water received in the lake was 49,087 millions of gallons, or 62·4 per cent. of the rainfall on the catchment area of 52·5 square miles.

Vehar Lake.—The rainfall for 1903 was 102·30 inches against 72·92 inches for 1902. The total quantity of rain which fell on the whole of the drainage area of 3,900 acres was about 9,051 millions of gallons, of which about 8,510 millions of gallons, or about 94 per cent. of the total rainfall, reached the lake.

Tulsi Lake.—The rainfall for 1903 was 129·16 inches against 93·19 inches for 1902. The total quantity of rainfall on the whole drainage area of 1,700 acres was 4,981 millions of gallons, of which about 4,454 millions of gallons reached the lake—this is about 89 per cent. of the total rainfall. During the year there was no burst in the mains of the Salsette Division.

Supply and Distribution.—In the body of the Executive Engineer's report will be found the descriptions of the several mains either laid or sanctioned. There were 70 bursts in different mains, 329 new connections were made, and 179 connections were cut off for various reasons. The total number of connections at the end of the year was 20,833, and the number of meters in use was 3,208.

Public Health.—The state of the public health during the year was somewhat worse than in the previous year. Exclusive of still-born the number of deaths was 50,513, being 2,099 more than in the previous year. There were 20,788 deaths from plague and 1,477 deaths from small-pox against 13,820 and 288 respectively in 1902. The Executive Health Officer describes in his report the measures adopted by him in combating the epidemics of plague and small-pox. The number of births registered during the year was 16,375, being 1,224 less than in the previous year.

ABSTRACT OF THE REPORT OF THE HEALTH OFFICER OF BOMBAY CITY FOR 1903.

(*Dr. J. A. Turner.*)

Births.—The number of births registered during the year was 16,375, being 1,224 less than in the last year and 3,332 more than the average of the preceding five years, giving a birth-rate of 21·10 per 1,000 of the population as against 22·67 during the corresponding period of the last year; of the total number of births 8,506 were males and 7,869 females, and 1,818 still-born births. The decrease in the number of births is due to the fact that a large number of people had left Bombay during the first five months of the year owing to the scare of plague, the mortality from which was very high during those months; rate amongst Parsees was 25·26 and amongst Europeans 14·34 as against 24·55 and 11·81, respectively, during the last year.

Mortality.—The number of deaths in the City of Bombay during the year 1903, exclusive of still-born, was 50,513, being 2,099 more than in the previous year, but 8,618 less than the average of the preceding five years, giving an annual death-rate of 65·09 per 1,000 of the population.

The mortality during the year under report, although more than in the previous year, was the lowest of the previous corresponding period of any year since 1898, as shown below, and was chiefly due to plague and small-pox:—

Year.	Total Number of Deaths.	Year.	Total Number of Deaths.
1898...	51,961	1901...	59,495
1899...	56,434	1902...	48,414
1900...	79,350	1903...	50,513

Plague Mortality.—As in the previous year, the control of all the plague measures was under the Health Department in the year under report. The mortality from plague commenced to rise, as usual, in the month of January, and reached its maximum on the 31st of March, and then declined. The number of attacks and deaths registered from plague during the year was 23,344 and 20,788 respectively, as against 16,423 attacks and 13,820 deaths during the previous year. The general Hindu community suffered severely from plague as in previous years, the number of deaths amongst this class being 13,288 as against 8,597 during the last year.

There was an increase in the number of deaths from plague in all the communities except Europeans and Negro-Africans, who show 8 and 4 deaths as against 13 and 9, respectively, during the previous year. There was a decrease in the number of deaths from plague in Girgaum, 1st Nagpada and Sewri Sections, the number being 471, 27 and 144, respectively, as against 576, 45 and 145 during the last year. In all the other sections of the city, there was an increase in the number of deaths from plague.

As regards the larger number of deaths in Worli Section, 1,884 as against 761 during the past year, I may point out that Worli is a large manufacturing district, as evidenced by the fact that it contains 35 large mills and one very large workshop belonging to the B. B. & C. I. Railway Company, where thousands of workpeople

are employed daily. The labourers naturally like to live as close to their places of work as possible, and hence the district is apt to be congested. It is a well-known fact that overcrowding is an important factor in increasing the number of deaths from plague.

Our difficulties in combating the plague during the earlier part of the year were aggravated by the presence of a woman at Worli who posed as a goddess gifted with the power of curing plague. Large numbers of people gathered round her residence and many plague patients were conveyed in public conveyances to her. As soon as this was brought to my notice, every endeavour was made to prosecute the woman, and the police, under Sections 268 and 269 of the Indian Penal Code, instituted the necessary proceedings. The Magistrate, in the first instance, acquitted the woman, and we were rendered helpless owing to the limited powers granted to the Health Officer, but subsequently an appeal having been made to higher authorities, further proceedings were instituted and the woman was convicted.

Out of 20,788 deaths from plague 13,288 were amongst males and 7,500 amongst females, as against 9,159 and 4,661, respectively, during the last year.

The highest plague mortality was recorded in the month of March, the number being 5,865, April coming next with 5,737; the lowest mortality was in November, 221 deaths being recorded.

In the following table it will be observed that there has been a marked decrease in the number of deaths from fevers, cholera, phthisis, diseases of the nervous system, diarrhœa and dysentery as compared with the figures of the last year:—

TABLE SHOWING THE NUMBER OF DEATHS AND THE DEATH-RATE FROM DIFFERENT CAUSES IN 1902 AND 1903.

Cause of Death.	1902.		1903.	
	Number of Deaths.	Death-rate per 1,000 of Population according to the Census of 1901.	Number of Deaths.	Death-rate per 1,000 of Population according to the Census of 1901.
Small-pox	288	·37	1,477	1·90
Measles	642	·82	1,115	1·43
Fevers	4,518	5·82	2,333	3·00
Cholera	75	·09	17	·02
Plague	13,820	17·80	20,778	26·78
Phthisis	3,957	5·09	2,842	3·66
Diseases of the Nervous System	3,027	3·90	2,282	2·94
„ Respiratory System	7,250	9·34	7,101	9·15
Diarrhœa	2,266	2·92	1,757	2·26
Dysentery	1,377	1·77	1,003	1·29
Accidents	732	·94	547	·70
All other Causes except Still-born	10,462	13·48	9,251	11·92
Total	48,414	62·38	50,513	65·09

By sexes, 28,934 males and 21,579 females died during the year. The highest number of deaths amongst males occurred in the age-period between 20 to 25 years, 3,484 deaths having been registered, and amongst females, like the previous year in the age-period of 15 to 20, 2,218 deaths having been registered. The lowest number of deaths amongst males and females occurred in the age-period between 4 to 5 years, 292 and 283 deaths respectively having been registered during the year.

Death-rate by classes.—The Jain community, which includes Banias, recorded the highest mortality, viz., 143·87 per 1,000 of population. Next came Lingaets, the death-rate amongst this class being 90·01. The general mass of the Hindu community give a death-rate of 68·66. Hindus, low-caste, show the death-rate of 68·23, and Musselman 66·05. The death-rate amongst Parsees was 29·56. European death-rate being less than the last year, viz., 15·48 as against 21·99. Negro-Africans and Buddhists, who form very small communities in the City, showed the death-rate of 65·49 and 37·97, respectively.

Small-pox.—From small-pox 1,477 deaths occurred during the year, as compared with 288 in the last year and 792 during the average of the previous five years. The disease prevailed in an epidemic form in the earlier part of the year and then subsided. It was feared that small-pox would again break out in the City in an epidemic form, and on the 19th December I immediately issued a circular to all the Divisional Health Officers and the District Registrars drawing their attention to it and requesting them to make strict enquiry and investigation into each case of small-pox and to remove all such cases to hospitals, to strictly disinfect the clothes, and persuade all unvaccinated contacts to get vaccinated; 13 cases of small-pox occurred in a chawl at De Lisle Road and 7 cases in another chawl at Curry Road occupied by mill-hands. The chawls were disinfected and the clothes sterilized. The patients were removed to hospitals and their rooms thoroughly disinfected. After a fortnight 184 persons from these chawls were vaccinated at the Municipal Dispensary at De Lisle Road. The prompt measures taken by the Divisional Health Officers in isolating the sick and disinfecting the buildings have checked the spread of the disease.

Cholera.—17 deaths from cholera were registered during the year, being 58 less than in the last year and 935 less than in the corresponding period of the preceding five years. The cases were of sporadic nature. Of the total number of deaths 11 occurred amongst Hindoos of other caste as against 47 in the previous year; 2 amongst Mussulmans as against 13 in the previous year; 3 amongst Hindus of lower caste, and 1 amongst Parsees as against 4 and 5, respectively, in the previous year; 2 deaths occurred amongst persons who had resided in Bombay for 3 months and under, and 2 amongst those who resided in Bombay for 6 months and under. Out of 17 deaths, 13 occurred amongst persons born out of Bombay.

Fevers.—The total of 2,333 deaths was registered from fevers during the year, as compared with 4,518 in the last year. Malarial fever, including ague and remittent fever, claims the highest number, viz., 2,288, being 2,141 less than the last year and 3,580 less than the average of the preceding five years. To enteric fever 45 deaths were registered, being 44 less than the last year and 13 less than the average of the preceding five years. The diseases, as in previous years, commenced rising from January to March. In February the highest number of deaths, viz., 254, were registered, and from the month of April the disease gradually declined till the end of the year. Excluding Negro-Africans and Buddhists, who form very small communities, there was a decrease in the number of deaths in all the other communities as well as in all the sections of the City.

The general mass of Hindu community show a remarkable decrease, the rate being 2·80, as against 6·02 in the previous year. Mussulman give the death-rate of 2·85 as against 5·21 in the previous year. From the statement given below it will be seen that the deaths registered from fever mortality are much lower than any of the previous years from 1894. This is due to the accurate registration of the causes of deaths, as every death is carefully inquired into by the District Registrar, and in many instances certificates from the medical men certifying the causes of death are received, thus a more accurate diagnosis is obtained.

STATEMENT SHOWING THE NUMBER OF DEATHS FROM FEVERS FROM 1894 TO 1903.

—	1894.	1895.	1896.	1897.	1898.	1899.	1900.	1901.	1902.	1903.
Number of deaths from fevers	6,458	6,404	8,776	6,951	4,114	5,063	7,928	7,921	4,518	2,333

Infant mortality.—The number of births registered during the year was 16,375, giving an infant mortality of 532·39 per 1,000 of the births. Small-pox and measles prevailed during the year in an epidemic form, and accounted for 436 and 441 deaths of infants under one year of age, respectively, as against 87 and 205 deaths in the previous year. Diseases of the respiratory system are stated as being responsible for 2,290 deaths amongst infants under one year of age as against 2,347 in the previous year. The other causes given are—Diseases of the nervous system, including "convulsions" 1,591, debility 2,570, of the latter 2,071 deaths were among infants under thirty days. Diarrhœa is responsible for 539 deaths amongst infants under one year of age.

APPENDIX.

No. 1.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT of the SANITARY COMMISSIONER with the GOVERNMENT of INDIA for 1903.

The Director-General, Indian Medical Service, in his capacity of Sanitary Commissioner with the Government of India, has hitherto prepared and signed the Annual Sanitary Report; but since the 6th of September, 1904, he has been relieved of the sanitary part of his duties, and the Report for 1903 appears under the signature of a separate officer, who retains the title of "Sanitary Commissioner with the Government of India." In the concluding paragraph of the Report the circumstances under which this change was effected are briefly described.

2. The meteorological features of 1903 do not appear to have differed widely from normal. As regards the rainfall, however, it is stated that it "was generally in excess in August, September, and October, and was irregularly distributed in the remaining months of the year." The harvests were, on the whole, abundant, and food prices slightly lower; but the health of the general population, as measured by the death-rate, was not so good as in the preceding year.

3. It might have been expected that the health of the European Army of India would have suffered, or at least would not have improved, whilst that of the surrounding population underwent deterioration. But, on the contrary, the returns show the sickness amongst both the European and Native troops to have been less than usual. In the European Army, the average strength of which had increased to 70,445 from 60,540 in 1902, the ratio of admissions into hospital was the lowest on record; and the ratios of constantly sick, of deaths, and of invalids were lower than those of the preceding year, as well as of the quinquennium 1897-1901. From plague, which was the main cause of the increased mortality amongst the general population, the European Army was comparatively exempt. Yet, small though the loss from this disease has, so far, been, the returns show that the risk of infection incurred by the troops varies, as in the case of most other epidemic diseases, in proportion to the intensity and extent of its prevalence amongst the general population. During the preceding year, when the deaths from plague amongst the native population numbered 583,937, two cases with one death were recorded among the European troops; whilst, during the year under report, when the deaths among the former rose to 865,578, twelve cases with two deaths were recorded among the latter.

4. As usual, malarial fevers and venereal disease were the chief causes of sickness; the former accounting for 23·9 and the latter for 23·5 per cent., of all the admissions into hospital. In the previous year the corresponding figures were 23·5 for malarial fevers and 26·0 for venereal disease; so that, whilst the percentage of admissions due to the former remained practically the same in both years, there was a marked decrease in the percentage due to venereal disease in the year under report. But, although the chief causes of sickness, these diseases were accountable for only an inconsiderable share of the total mortality. The deaths due to malarial fevers, or to ague and remittent fever together, numbered 41; whilst 10 were credited to venereal disease. The chief causes of death continued to be, as in the preceding year, enteric fever and hepatic abscess; the former accounting for 291 and the latter for 91 of a total of 896 deaths from all causes. Between them, these two diseases were credited with a percentage of 42·0 of all the deaths in the European Army of India, or almost the same as in the previous year. The mortality from nearly all the other death causes, excepting cholera and small-pox, showed a substantial decrease; the total ratio of deaths, per thousand of average strength, from all causes falling to 13·05 from 14·68 in 1902. Accompanying the lower rates of sickness and mortality, there was a marked decrease in the proportion of men invalided. This fell from 37·25 per thousand of strength, in 1902 to 29·29 in the year under report. "There was a remarkable decrease in the number of men "sent home on account of secondary syphilis and debility." Judged by the returns, the health of the troops in all of the four Commands was better in the year under report than in the previous year, except in the Madras Command, where there was no change. The Sanitary Commissioner graphically sums up the comparative result for 1903 and the preceding year in these words:— "If the sickness, mortality and invaliding rates had been the same as those of the preceding "year, there would have been 3,162 more men admitted to hospital, 220 more constantly sick, "115 more deaths, and 561 more men invalided."

5. Among the chief diseases from which the Army suffered during the year, *influenza* finds a place; but although credited with an admission rate of 3·1 per thousand of strength, as compared with only 1·8 in the preceding year, no death was directly ascribed to it.

6. *Cholera*, from which the European Army had enjoyed remarkable immunity during the two preceding years, increased synchronously with the increase of the disease among the general population during the year under report. Whilst in 1901 there were only 12 cases, and in 1902 only 3, all of them fatal in both years, the number rose in the year under report to 81 attacks, with 57 deaths. Going back to 1900, a year in which cholera prevailed with unprecedented violence amongst the general population, the number of European soldiers attacked was 107, and of these 88 died. Although unremitting attention to every sanitary detail affecting the soldier

has succeeded in steadily reducing his liability to cholera, until the ratio of attacks has fallen from 5·4 per thousand of strength in the five-year period 1875-79 to only 0·8 in the period 1901-03, the close connection shown by the returns to exist between the rise and fall of the disease amongst the native population and its rise and fall in the armies of India would hardly encourage the hope that it can be completely eradicated from the Army so long as it continues to prevail, with but little abatement, amongst the people of the country.

7. If *small-pox* is the preventable disease which is is generally believed to be, and if its prevention can be secured by efficient vaccination and re-vaccination, the returns of sickness and mortality during recent years would seem to suggest the need for inquiry into the cause of its increasing prevalence in the European Army of India. Beginning with 1898, the returns show that two attacks, with no death, occurred in that year. In the following year there were 14 attacks, with one death; in 1900 the attacks increased to 36, and the deaths to 3; in 1901 the number of attacks fell to 20, whilst the number of deaths remained at 3; in 1902 the attacks again slightly increased to 23, and the deaths to 4; whilst now, in the year under report, the number of attacks have sprung up to 68, and the deaths to 8. During those years the mortality from small-pox among the general population has also increased, the number of deaths due to it ranging from a minimum of 53,347 in 1899 to a maximum of 115,603 in 1902. Doubtless there is an intimate connection between this increased prevalence of the disease amongst the native population and its increase amongst the troops stationed in its midst; but experience has proved that death from small-pox, instead of being not uncommon, is extremely rare in the case of persons who have been efficiently vaccinated and re-vaccinated. The protection of the native population by vaccination, which would indirectly conduce to the protection of the Army also, has been seriously interfered with by the epidemic of plague from which India has been suffering since 1896.

8. A slight decrease in the ratio of admissions and deaths from *ague* is recorded. The ratio of admissions, which had been 247 per thousand of strength in the previous year, has fallen to 243 in the year under report; the ratio of deaths falling at the same time from 0·5 to 0·34. To what extent these results may have been influenced by the measures adopted for the destruction of infection-bearing mosquitos is uncertain. The Sanitary Commissioner writes: "There can be "no doubt that the efforts put forth during the past year have been far more general, more com- "plete, more consistently and energetically maintained, and better organized than heretofore. "At the same time signs are not wanting that in many respects the work has yet to be developed "in its range and in completeness, before we can hope for measurable results." The measurement of results, it may be anticipated, will not always be easy. The sickness due to malarial fevers in stations will be liable to vary from year to year independently of the abundance, or even absence, in them of infected mosquitos. It is stated that, in at least 13 stations, a careful search failed to discover *anopheles* of any kind; yet the troops in those stations did not enjoy immunity from malarial fever. In such cases it may be assumed that the disease was imported by men who had been infected elsewhere. Varying climatic conditions, especially those connected with the amount and regularity, or irregularity, of the season's rainfall, may be expected to exercise an effect on the results which it will be difficult exactly to determine. The administration of quinine as a prophylactic is another factor which will have to be taken into the reckoning. So far, "the dose, the interval between doses, the method and period of administration have varied "in almost every instance, and very few medical officers have committed themselves to an opinion "of its value."

9. Of the chief diseases, *enteric fever* continued to be the most fatal. Although responsible for only 19·6 of a total ratio of 1,033·4 admissions, the ratio of deaths due to it was 4·19 of a total of 13·05; that is to say, it was the cause of close upon one-third of the entire mortality of the year in the European Army of India. The enteric fever admission-rate was considerably higher than in the previous year; but the death-rate was fractionally less. That the mortality caused by it during the year was no higher is matter for satisfaction, in view of the high proportion in the Army of men of the age and length of service in India when they are most susceptible to attack. Of the average strength, 51 per cent. were under 25 years of age and 25 per cent. had less than one year's service in India. Of the section of the Sanitary Report devoted to an account of the health of the European Army of India during the year, just one-half is taken up with a history of enteric fever; an allotment of space not disproportionate to the importance of the disease as a cause of sickness and mortality. The list of papers and books appended to the section will afford some idea of the labour which must have been involved in the preparation of the concise sketch given of the latest researches carried out with the object of throwing fresh light on the causation and prevention of this disease. Perusal of the sketch does not leave the impression on the reader that any very definite advance has been made during the past year in our knowledge of these questions. At the time this *memorandum* is being written, a severe epidemic of enteric fever, from which Lincoln, a town of about fifty thousand inhabitants, has been suffering, is undergoing investigation at the hands of scientific observers, and the results recorded from time to time in the medical journals. The most striking feature in the account given of the epidemic, in the course of which 815 persons have already been attacked, is its remarkable similarity to the accounts given of preceding epidemics of enteric fever. There is a sudden and widespread outbreak, suggestive of some common source of infection. The water-supply is suspected, and a bacteriological and chemical examination confirms the suspicion that the disease has its origin in, and is being disseminated by, water containing the *materies morbi*. Immediate steps are adopted for the purification of the water-supply, and, after two or three weeks, the number of people attacked begins to diminish. As a consequence of the measures taken for its purification, the water "now sent into consumption" is shown by analysis to be "innocuous"; but, unfortunately, cases of the disease still continue to recur, and in no inconsiderable number. This persistence of the epidemic after the water has been pronounced to be "innocuous" has to be accounted for; and "the 145 cases since 17th February" are said to have been "probably

"all secondary cases"; that is to say, "attributable to direct or indirect infection from the "primary cases." The specific germs of enteric fever must have been present in the water before the outbreak; yet, although it may be assumed that the water-supply of the town was periodically submitted to bacteriological and chemical examination, it was not until after an extensive outbreak of the disease that the discovery of its specific contamination was made. Even so slight a sketch may help to indicate how little the latest methods of procedure in dealing with an outbreak of enteric fever have been affected by fresh knowledge of the disease gathered from the voluminous records of recent scientific research.

10. Whilst the admission-rate from *tubercle of the lungs* remained the same as last year, the death-rate from this cause was the lowest on record; the 17 fatal cases yielding a ratio per thousand of strength of only 2·4. From *pneumonia* there were 40 deaths, and from *other respiratory diseases* 15, the ratio of mortality in the case of the former disease being much, and in the case of the latter diseases being slightly, below the ratios recorded in the previous year.

11. From *dysentery* there were 49 deaths, giving a ratio of ·70 per thousand of strength, as compared with ·69 in the previous year. No fatal case of *diarrhœa* was recorded. Next to enteric fever, *abscess of the liver* was the most fatal of all the diseases and the cause of 91 deaths, or equal to a ratio of 1·29 per thousand of strength, as compared with 1·85 in 1902. As in the previous year, Naini Tal and Barrackpore were the two stations which, in proportion to the strength of their garrisons, suffered most from this disease. Dysentery, between which and hepatic abscess an intimate connection frequently exists, was also exceptionally prevalent in both stations.

12. Last year's returns showed that the reductions annually recorded in the number of admissions from venereal disease since 1895 had at length received a check and been even replaced by a slight increase. Fortunately, this set-back has proved to be only temporary, and the reduction has recommenced in the year under report; the admission-rate falling to 247 per mille of strength. "One must go back to 1897 to find a lower rate than that of the year under "review." But, when in this year of much reduced admission-rate, the returns still show that 1,569·49 men were constantly sick on account of venereal disease, it will be realized how much of the inefficiency of the Army still continues to be due to this one cause. Of all the measures adopted with the object of abating this disease in the Army, none is likely to be more effectual than the education of the soldier. His misfortunes are largely due to his ignorance. As the Sanitary Commissioner says:—"We must look to the education of the men who suffer largely "through ignorance and lack of self-control, which are the results of the environment from "which they are mostly drawn; and the lectures which are now a feature of many regimental "institutes are a sign that this is becoming appreciated."

13. The health of the *Native Army*, of an average strength of 124,660, or almost the same as in the previous year, was exceptionally good, the returns showing a decrease in the ratios of admissions into hospital, of constantly sick, of deaths and invaliding. As in the case of the European Army, *intermittent fever* was also a chief cause of sickness in the Native Army. The admission rates from this disease were nearly the same in both armies; amounting to 242·6 per thousand of strength amongst the European, and 247·4 amongst the Native troops. But in respect of the other chief cause of sickness in the European Army, *venereal disease*, the ratios of admissions due to it in the two armies differed widely; the ratio in the European Army having been 247·0 per thousand of strength, and in the Native Army only 24·5. It was in no small part due to the comparative immunity of the Native troops from this disease that their admission rate for the year was only 622·0 per thousand of strength, against 1,033·4 for European troops. If venereal disease were excluded from the returns, the admission rate from all other causes would be 637·5 for the Native and 786·4 for the European Army. Still more striking is the contrast between the rates of admission from *enteric fever* in the two armies. Whilst a ratio of 19·6 admissions per thousand of strength is recorded from this disease in the European Army, a ratio of only ·6 is recorded from it in the Native Army.

14. Of the chief diseases, *influenza* and *cholera*, the former was the cause of a somewhat greater, and the latter of the same, rate of admissions into hospital in the Native as compared with the European Army. The most severe outbreak of cholera occurred at Mian Mir, where, of 34 men attacked, 29 died. Infection was attributed to the use for drinking purposes of canal water which is liable to pollution by native civilians. The death-rate from cholera amongst the native troops of the Bengal Command is traced, in the records of six consecutive periods of five years each, from 1870 to 1900, showing that it has fallen from 1·1 per thousand of strength in the first of those periods to 0·9 in the last, and still further, to 0·34 in the three years 1901-03. The fall has been by no means regular, nor very marked until the last three-year period 1901-03 is reached. Taking the six complete periods of five years each, the death-rate for the first was exceeded in two of those that followed, was less in other two, and the same in one.

15. From *small-pox* the Native suffered less than the European Army. Whilst in the former the admission rate was only ·6 per thousand of strength, with two deaths, it was 1·0 with eight deaths in the latter. These results are unusual and contrary to what might have been looked for.

16. Although the admission rate due to *intermittent fever* fell from 274·5 in the previous year to 247·4 in the year under report, it accounted for 37 per cent. of all the admissions. It was, however, responsible for only 82 deaths, or a ratio of ·66 per thousand of strength. *Remittent fever*, on the other hand, whilst the cause of the comparatively small admission rate of 8·6, accounted for 110 deaths, yielding a rate of ·88, or nearly 9 per cent. of the total mortality in the Native Army. Both types of fever were much less prevalent during the year under report than in the preceding decade.

17. According to the returns, *enteric fever* was somewhat more prevalent and fatal in the Native Army than in the preceding year. As the Sanitary Commissioner puts it: "The admission "rate on account of enteric fever has shown a tendency to a small but regular and definite "increase during the last few years." Whether this increase is the result of a growing prevalence of enteric fever amongst the native troops, or only of altered methods of diagnosis, is uncertain. The admission and death-rates of ·6 and ·22, respectively, ascribed to the disease, are still insignificant in comparison with those recorded in the European Army. The greater liability of the Gurkhas than of the other soldiers of the Native Army to suffer from enteric fever is, again, clearly brought out in the returns. In the Army Department Medical Report for 1902, page 210, the writer repeats a theory sometimes used to account for the comparative immunity of the natives of India from enteric fever. "Natives," he says, "are saturated in "enteric fever from childbirth and become immune. The germs are always in their surroundings, "and are thus attenuated for them and virulent for Europeans." Statements of this nature are not infrequently made, but without the evidence on which they are based. If the statistics furnished by the Secretary of State for War may be relied on, the enteric fever "germs" would appear to be no less abundant and virulent in some other parts of the world than in India. Replying, a year ago, to a question put to him in Parliament by Dr. Farquharson, he stated that, whilst during the war in South Africa 719 officers and 6,863 non-commissioned officers and men were killed or died of wounds, no fewer than 183 of the former and 7,807 of the latter died of enteric fever.

18. The extension of the *plague* epidemic has not been accompanied by a corresponding increase in the number of cases of the disease amongst the soldiers of the Native Army; but the mortality due to it was the highest yet recorded in any one year. During the preceding year the attacks numbered 192 and the deaths 95; whilst in the year under report the attacks fell to 184 and the deaths rose to 115.

19. *Tubercule of the lungs* was accountable for 730 admissions into hospital with 85 deaths. The greater prevalence and fatality of the disease amongst Gurkhas than amongst the rest of the soldiers of the Native Army is clearly brought out in the returns. Whilst for the Native Army, excluding the Gurkha Regiments, the admission rate from this disease was 3·2 and the death-rate ·43, for the Gurkha Regiments, by themselves, the admission rate was 28·9 and the death-rate 2·8 per thousand of strength; that is to say, the Gurkhas were nine times more liable to attack and nearly seven times more liable to die of tubercle of the lungs than the other soldiers of the Native Army. Dealing with the question of the best means for preventing, or diminishing, the destructive effects of lung diseases amongst our Gurkha soldiers, the Sanitary Commissioner says: "There can be little question of the advisability of moving as many of the "men as possible to the plains during the winter; life in the open air and nights passed under "canvas or in permeable huts, given ample space per unit, would certainly prove the best pre-"ventive of phthisis and other lung diseases which put such a heavy tax on the efficiency of the "Gurkha sepoy." The mortality from *pneumonia* and other *respiratory diseases* was somewhat less than in the previous year; but, between them, these diseases accounted for 36·3 per cent. of the total mortality for the year in the Native Army. The troops stationed in the Hills along the North-West and West Frontier of India suffered most.

20. The marked decrease in the ratios of sickness and mortality due to *dysentery and diarrhœa* is a noteworthy feature of the returns for the year. The admission rate from dysentery has fallen 25 per cent. and the death-rate by about 50 per cent. below the decennial means; "and, indeed, these are the lowest on record." The incidence of the disease varied widely in accordance with the part of the country occupied by the troops, and "may furnish," the Sanitary Commissioner remarks, "another instance of the fact that sickness is least prevalent where the "Sepoy is most at home."

21. The admission rate of 24·5 per thousand of strength from *venereal disease* in the Native Army for the year under report is the lowest on record. The contrast between the prevalence of this disease in the different Commands is striking. Whilst the Native soldiers serving in the Madras and Bombay Commands had 31·0 and 33·4, respectively, per thousand of their strength, admitted into hospital from venereal disease, those serving in the Bengal Command had 22·5, and those serving in the Punjab only 17·2. This comparative immunity, the Sanitary Commissioner says, is doubtless due to the fact that the men are serving close to their homes in the latter two Commands. The Gurkhas, as usual, suffered more from venereal disease than the rest of the Native Army; their admission-rate having been 38·7 per mille, as compared with only 13·6 for the troops (excluding Gurkhas) in the Punjab Command. But although the Gurkha soldier, who may be considered an alien, suffered more than the native soldier, who has his home in the country in which he is serving, he was six times less liable to contract the disease than the British soldier, who is likewise an alien. The latter, however, even in his home in Great Britain, is a victim to venereal disease far more frequently than either the French or the German soldier. Whilst our Home Army records an admission-rate from venereal disease of 122·7 per thousand of strength, the rate in France is 33·5, and in Germany only 18·1.

22. The Section on the Jails of India discusses in a very thorough manner the conditions under which the health of the prisoners, as disclosed by their vital statistics, has steadily improved during the last quarter of a century. The rate of mortality among the prison population, traced through the last four quinquennial periods of the century just closed, is seen to have fallen from 35·96, in the first of these, to 29·97 in the last. During the past three years 1901-1903, the fall in the death-rate has been much more rapid; in the first of these it was 26·87; in the second 24·85; and now, in the year under report, 21·38, or lower than the estimated death-rate of an equal number of the free population of the same ages as the prisoners. The main causes of this remarkably low death-rate in 1903 was, doubtless, the decrease in the average number of prisoners consequent upon the prosperous character of the season. The Jail population, which

had been of an average strength, during the previous eight years, of 118,485, fell in the year under report to 105,729. Not only is a season of abundant harvests accompanied by a decrease of crime and, consequently, of jail population, but the prisoners received into jail in such a year are in a better condition of health than those admitted in a year of scarcity or famine. Their smaller number, likewise, ensures them more space during their confinement, a condition in itself favourable to health.

23. As in the case of the European and Native Armies, the prison population suffered more from *cholera* during 1903 than in the previous year, but there was no serious epidemic; the total number of deaths due to it having been only 57, or 33 more than in 1902. *Small-pox* caused 6 deaths, or the same number as in the preceding year. The measures which in previous years had been successful in excluding *plague* from the jails were no less effectual during the year under report. "Of the total number of jails, 245, no less than 159 were situated in infected towns or "districts, and of these only 14 returned cases of the disease, eight jails recording only one case "each." *Enteric fever*, to judge from the number of prisoners attacked by it, was less prevalent than in the preceding year. In the year under report, the diagnosis of enteric fever was made in 45 cases, as compared with 69 in the previous year; but, whilst of the former number 25 proved fatal, only 15 were fatal in the much larger number of cases in 1902. "The disease "appeared in 28 jails, of which 21 had only one case each." And yet, seeing that the inmates of a jail are subjected to the same conditions of existence, all partaking of the same supplies of food and water, and in daily communication with each other within a limited area, one would expect that a source of infection which would give rise to one case would give rise to more than one. The enteric fever death-rate amongst prisoners differed but little from that in the Native Army. Amongst the former it was ·25 and in the latter ·22. Whilst *intermittent fever* was the cause of, by far, a higher ratio of admissions into hospital than any other disease, the chief causes of death were, as usual, *tubercle of the lungs, dysentery,* and *pneumonia.* Intermittent fever accounted for an admission rate of 363·6 per thousand of the average strength of the jail population, or 40·88 per cent. of the admissions from all causes; and, between them, tubercle of the lungs, dysentery, and pneumonia were the cause of considerably more than half the number of deaths among the prisoners during the year. From those scourges of Indian jails, *dysentery and diarrhœa,* there was a marked decrease of mortality, the combined death-rate caused by them falling to 4·66 per thousand of the jail population, as compared with 6.57 in the preceding year. The striking decrease of sickness and mortality in the jails of India is a satisfactory feature of the sanitary history of the year.

24. The subjects discussed in the remaining sections of the Report, are separately dealt with in our *memoranda* on the several Provincial Sanitary Reports, and need not be referred to again in this place.

5th June, 1905.

No. 2.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bengal for 1903.

The Report begins with a brief but useful account of the year's rainfall. For a province covering so vast an area, no general statement regarding its rainfall would apply to every part of it. Whilst from January until May, the northern districts suffered from a deficiency of rain, the south-western districts had heavy falls during the first two months of the year. During April and May the rainfall was in defect throughout the province, except in Chota Nagpur. Following this deficiency, the temperature was excessive; the period from the middle of April, and continuing into May, having been one of the hottest on record. Monsoon conditions were established during August and rain fell, in some parts in defect and in others in excess, until its final cessation in December, which was practically a rainless month. Compared with that of the previous year, the rainfall was greater in 13 districts of the province and less in 32. "The agricultural outturn of the year under report was rather below normal, or lower than that "of last year in 25, about normal in 12, and above normal in 8 districts." The smaller yield of the harvests was, however, more than counterbalanced by the absence of any large export of grain to other provinces; with the result that the prices of the chief food grains were lower almost everywhere than in the preceding year. The comparative dryness of the season and cheaper food were favourable to the public health; and, in spite of a large increase in the mortality from plague and cholera, the total number of deaths was somewhat less than that recorded in 1902.

2. The *birth-rate*, which had been 40·14 per thousand in the previous year, fell to 39·0 in the year under report. It was, thus, 12·8 below that estimated to be "the probable true normal rate" of 51·8 per thousand of population for Bengal. It was greatly exceeded in the United Provinces of Agra and Oudh, as well as in the Central Provinces; the former recording a rate of 46·13, and the latter of 45·11. During the same year the birth-rate in England and Wales, according to the returns published by the Registrar-General, was only 28·4. In commenting on the slight decrease in the birth-rate in Bengal from 40·14, in the previous year, to 39·0 in the year under review, the Sanitary Commissioner says: "This unsatisfactory result was "undoubtedly due to the great unhealthiness of the year 1902." It may well be doubted if the slight fall in the birth-rate can be regarded as "unsatisfactory" in a country which records the deaths of 203·5 male children in the first year of life, out of every 1,000 born, and of 185·1

female children, out of every 1,000 born. In England and Wales, with their lower birth-rate, the number of infants dying during the first year of life, out of every 1,000 born, both sexes inclusive, was 132. In England and Wales a declining birth-rate is accompanied by a declining death-rate and a declining rate of infant mortality. There seems to be no reason to doubt that a decline in the birth-rate in Bengal would similarly be accompanied by a fall in the death-rate at all ages and especially amongst infants. To the unrestrained fecundity, which results in the introduction into existence of a greater number of children than their parents have the means of properly rearing, is due, more than to any other cause, the excessive infant mortality which the Government deplores. The effort to bring up children in excess of the number for which suitable provision can be made, not only leads to the waste of much infant life, but by increasing the poverty of the family, tends to enfeeble and stunt the survivors.

3. The *death-rate* remained nearly the same as in the preceding year, showing only a fractional decrease in the year under report; a rate of 33·3 was recorded against a rate of 33·43 in 1902. Although, owing, doubtless, to the comparative dryness of the year, fever was less fatal, the decrease from this cause was largely counterbalanced by increased mortality from plague and cholera. The contrast between the birth and death-rates in urban and rural circles is striking. Whilst in town areas the birth-rate, as recorded in paragraph 8 of the Report, was only 23·74 per thousand of population, in rural areas it was 39·81. With a far lower birth-rate, towns might have been expected to record a lower death-rate than the country; but, on the contrary, the death-rate recorded in town circles was 36·39 per thousand of population, and only 33·17 in rural areas. From which it may be concluded that the measures taken to improve the sanitary condition of the towns, but not yet generally extended to rural areas, have failed to compensate for the site-crowding and other conditions inimical to health prevailing in towns. The Sanitary Commissioner writes: "As usual, the mortality from cholera, plague, dysentery, "and diarrhœa and other causes was higher in urban than in rural areas. This was also the "case with respiratory diseases which stand a much better chance of correct diagnosis in towns "than elsewhere." Whilst registration of deaths according to their exact causes is still so unreliable, it is unsafe to draw from the returns conclusions as to the mortality caused by each separate disease in towns, as compared with the mortality caused by the same disease in rural areas. The Sanitary Commissioner says that "fever continued to prevail with greater intensity "in rural areas owing evidently to the existence in them of the conditions favourable for the "generation and prevalence of malarial fever"; but it is probable that this may, at least in part, be due to a greater number of deaths from other causes being lumped together under the head of "fever" in the returns from villages, the inhabitants of which may be assumed to be less educated, than in the returns from towns, the inhabitants of which may be assumed to be more educated. The mortality returns for Calcutta may fairly claim to a nearer approach to accuracy than those for the other towns of the province. Comparing the former with the latter, it is seen that, whilst the death-rate of Calcutta is nearly the same as that recorded for the rest of the Bengal towns, the ratios of deaths assigned to the several diseases differ widely. In Calcutta, for example, fever is credited with a death-rate of 5·74 per thousand of population; whilst in the rest of the Bengal towns it is credited with a death-rate of 16·77. On the other hand, whilst respiratory diseases have attributed to them a death-rate of 3·99 in Calcutta, they are recorded to have been the cause of only 0·15 in the other Bengal towns. It is unlikely that differences so wide can be due to difference in the incidence of these diseases in Calcutta as compared with the other Bengal towns.

4. *Chief Diseases.*—The Sanitary Report, as noted in the Government review of it, deals, for the most part, with figures only; information as to the special causes and prevalence of disease is somewhat scanty. From *cholera* there was a serious rise in the mortality; over two hundred thousand deaths having been attributed to it as compared with just over one hundred and fifty thousand in the previous year. According to the reports of Civil Surgeons, pollution of the drinking-water supply, consequent upon the late commencement of the monsoon, is said to have been chiefly concerned in bringing about this increase. As usual, reference is made to the influence of anti-cholera inoculation in rendering the coolies annually despatched to Assam immune from the disease. The Sanitary Commissioner, in paragraph 8 of his Report, says: "The returns received from the Superintendent of Emigration, Calcutta, showing the number "of cases of cholera among uninoculated and inoculated coolie emigrants on board the steamers "proceeding from Goalundo to Dibrugarh during January to September, clearly show the "advantage of being inoculated against cholera." According to these returns, out of 2,633 uninoculated coolies, 68, or 2·58 per cent., were attacked by cholera, 16 of the cases proving fatal; while out of the 199 inoculated coolies who were on board these steamers, only four, or 2·01 per cent., got the disease, one of the patients succumbing to it. These figures do not appear to support very strongly belief in the advantages of anti-cholera inoculation; but the numbers are too small for safe conclusions to be founded on them.

5. *Small-pox*, which had prevailed "with unprecedented virulence" during 1902, was still accountable for upwards of thirty thousand deaths, giving a ratio of deaths of population, of ·40 as compared with ·70 in the previous year. After a year of high mortality from small-pox, the disease tends to die out as the unprotected subjects become fewer, owing to their having had small-pox, or having been vaccinated. In the absence of adequate vaccination, however, the unprotected will re-accumulate, and under conditions favourable to its outbreak, another epidemic will succeed the former one, its severity being determined by the proportion of the population remaining unprotected by vaccination, inoculation, or a previous attack of small-pox. The periodical recurrence of small-pox epidemics referred to in the Government review of the report on vaccination might thus find an explanation. As to the insufficiency of the protection of the people of Bengal there can be no question. Figures were given in our last year's *Memorandum* showing the number of children under one year of age annually vaccinated and the number who remained unvaccinated. During the year under report, the number of children under one year

of age returned as having been successfully vaccinated was 877,810, and the number available for vaccination, but not vaccinated, 1,562,866. Such figures speak for themselves. The Lieutenant-Governor "is constrained to conclude, from the facts before him, that the Department "as at present organised, is unable to cope with the disease." The widespread prevalence of small-pox, he adds, emphasises the necessity for thorough reform.

6. The mortality from *plague* was almost double that recorded in the previous year. A striking feature of the history of the disease was its unequal distribution. In the single district of Saran no fewer than 25,571 deaths out of a total of 65,680 for the entire province, were attributed to plague, giving a ratio of 10·61 per thousand of population, as compared with the provincial ratio of ·88. Calcutta with a death-rate of 9·69, and Patna with one of 7·19 were the only other districts in which the mortality from plague was excessive. The Civil Surgeon of Saran, the district which suffered most severely, reported that when rats began to die in a village the inhabitants called for disinfection, and evacuated the village, building temporary shelters close by. This last, he says, has been done very largely throughout the district; but he adds, "generally, the attitude is marked apathy to the disease." The Magistrate of the neighbouring district of Patna, which, as already stated, was one of the chief sufferers from plague, writes: "The only efficient check is evacuation in rural areas. The people are year by year becoming "more ready to adopt this by themselves." Of anti-plague inoculation, he says, "the educated "community as a whole in Patna are shy on account of the Punjab mishap."

7. The comparative dryness of the year doubtless contributed towards a reduction in the mortality from *fever*. The ratio of deaths per thousand of population, due to this cause, which had been 23·13 in the previous year, fell in the year under report to 22·23, but was still slightly higher than the average for the ten years 1893-1902. In dealing with the question of fever prevalence, the Lieutenant-Governor thinks that the people generally, even those who are educated, including Europeans and many medical officers, do not yet appear to have grasped the importance of measures having for their object the destruction of infection-bearing mosquitos. The most feasible means of diminishing the number of mosquitos would appear to be to deprive them of their breeding places by a system of drainage. The Lieutenant-Governor fully realizes the difficulties which will have to be overcome in carrying into practice the destruction of mosquitos "in a country such as Lower Bengal, where every hollow is a tank, and every ditch "a breeding place" for these insects; but thinks that even a decrease in the malaria-infected mosquitos is an object worth striving for.

8. The mortality from *dysentery and diarrhœa* shows no great variation from year to year. The returns would indicate that these diseases are more fatal in towns than in rural areas; but they may perhaps only indicate that they are better diagnosed and more accurately recorded in towns than in the country. So far, the endeavour to separate deaths due to *respiratory diseases* from other causes of death, has not met with much success. The returns of mortality from these diseases yield the incredibly small ratio of only ·10 per thousand of population for the province as a whole. Whilst towns record a ratio of 1·02 deaths per thousand of population, from respiratory diseases, rural areas return a ratio of only ·05 from the same cause. It is unlikely that the inhabitants of towns suffer twenty times more severely from respiratory diseases than do the inhabitants of country areas. But, here again, as in the case of dysentery and diarrhœa, the greater mortality from respiratory diseases in towns as compared with the country, which the returns would indicate, is probably only apparent and may be due, in part, to better differentiation of the causes of death by the more intelligent towns' people than by the less intelligent rural population.

9. The total expenditure on *sanitary works* in towns fell somewhat short of four lakhs of rupees; but exceeded the expenditure of the previous financial year by upwards of half a lakh. On the other hand, the total amount expended on these works in rural areas shows a decrease of upwards of eighty thousand rupees. The table given in Appendix II, page xxviii, to show the effect on the public health of important drainage and water-supply schemes carried out in Bengal, might lead to the conclusion that little, if any, benefit has followed the execution of these works. In 9 of the 19 towns mentioned in the table, decreased mortality is recorded since the completion of these sanitary works; whilst in the rest increased mortality is recorded. The explanation of these unexpected results is no doubt to be found in the steady improvement which has been taking place in registration of vital statistics since 1892. Year by year deaths omitted from the returns have become fewer, with the obvious consequence that the death-rate has shown a corresponding increase over the death-rate recorded in previous years when the deaths omitted from the returns were more numerous. A promising scheme for the systematic cleansing of villages is being carried into effect in the Patna district, and appears, so far, to have yielded good results. With a view of encouraging the villagers to interest themselves in the improvement of their village water-supplies, the Government have promised to contribute grants-in-aid to the extent of one-third of the cost of works undertaken for the purpose of improving the sources of supply and removing the causes of contamination. Without the co-operation of the people, substantial and enduring progress in village sanitation need hardly be looked for.

3rd June, 1905.

No. 3.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the United Provinces of Agra and Oudh for the year 1903.

The mortality of the year was unusually great, the death-rate rising to 40·28 per thousand of population, as compared with 32·54 in the preceding year, and with 30·91 the mean of the preceding five years. Only to a limited extent would the climatic conditions of the year appear to have been accountable for this increase. It is true that the mortality ascribed to fever and bowel complaints was considerably higher than usual, and that the late termination of the rains is considered by the Sanitary Commissioner to have affected this result; but the great rise of the year's death-rate was chiefly due to the destructive effects of two infectious diseases, plague and measles. During each of the first five months of the year rain was in defect, especially during April, when there was practically none except in the hills. The monsoon broke in June, but was at first nearly everywhere intermittent, and yielded an amount of rain much below normal. Similar conditions prevailed throughout the following month, both June and July being, in consequence, much hotter than usual. The months of August, September, and October recorded a rainfall more or less in excess of normal, unusually heavy storms of rain taking place in October over nearly the entire province, excepting a very few of the western and submontane districts. November and December were rainless.

2. A *birth-rate* of 46·13 was recorded for the year, against 45·84 for 1902, and 42·60 the mean for the previous five years. The accompanying *death-rate* was 40·28 as compared with 32·54 in the previous year, and with 30·91, the quinquennial mean. The high birth-rate was doubtless one of the contributory causes of the high death-rate; for the returns show that, of the total of 1,920,903 deaths at all ages, no fewer than 603,640, or not very far short of a third, occurred amongst infants of less than a year of age. Calculated on the number of children under a year of age living at the time of taking the last census, the infantile death-rate works out to no less than 409·93 per thousand; but calculated on the 2,200,031 births registered during the year under report, the ratio falls to 274·4. As the result of special inquiry, made in accordance with the orders of Government, for the purpose of ascertaining the cause of the high mortality amongst infants in the United Provinces, the Sanitary Commissioner shows that a wide-spread epidemic of measles, together with the respiratory and other affections so often a sequel of this disease, carried off large numbers of the very young during the year under report. The deaths from measles increased from a total of 15,292 in the previous year, to no less than 98,112 in the year under review. Plague, malaria, and small-pox, he adds, also contributed to swell the infantile death-rate. In the municipal towns of the province the death-rate amongst children under one year of age averaged 350·67 per thousand births, as compared with the provincial rate of 274·4. In several towns the number of deaths of infants did not fall far short of half the number born; and in one town, Pihani, the rate was 531·44. This town, it may be observed, also recorded the highest birth-rate. The ratio of mortality at all ages in urban areas greatly exceeded that in rural areas. In the former it reached 54·86 per thousand of population, as compared with 39·16 in the latter.

3. As usual, in the Sanitary Report of these Provinces, a return is given of deaths verified according to their causes by medical officers, medical subordinates, and medical practitioners. Of 11,228 such deaths, 1,346 are attributed to malaria fevers, 1,620 to dysentery and diarrhœa, 1,215 to pneumonia and other respiratory diseases, and 1,791 to plague. These numbers, as compared with the total mortality, are, as the Sanitary Commissioner remarks, too small to possess very much value; but taken for what they are worth, they tend to show that, in the general provincial returns, many deaths probably continue to be recorded under the head of "fever," which were in reality due to other causes. In the provincial returns, for example, fever as a cause of death has assigned to it a death-rate of 24·51 per thousand of population, against 0·58 from dysentery and diarrhœa, whereas, according to the figures furnished by medical practitioners, more of the deaths verified by them were due to the latter diseases than to fever. The extensive testing of the entries made in the birth and death registers continues to bear testimony to the comparative accuracy with which, as regards mere numbers, births and deaths are recorded in these provinces.

4. Owing mainly to an outbreak of *cholera* at the time of the dispersion of the crowds at the Great Fair at Hardwar on the 16th of April, the mortality caused by this disease showed a marked increase during the year under report; the total number of deaths ascribed to it increasing to 47,159 from 25,160 in the preceding year. A somewhat similar outbreak, followed by far more fatal consequences, occurred at the great Hardwar Fair of 1867, when the vast concourse of people had already begun to disperse after the chief bathing day. Regarding the outbreak in the year under report, the Sanitary Commissioner writes: "The great bathing day on the 13th was attended by "some 400,000 of people, and all went well until the 16th when some three-fourths of the people "had dispersed and the general sanitary arrangements were being broken up." This would seem to suggest the prudence of maintaining at these fairs the sanitary arrangements intact until after the complete dispersion of the crowds of visitors. On their way from Hardwar to visit other sacred places in the hills, the pilgrims carried with them the disease into the adjoining district of Garhwal, more especially, and to a less extent, into the more distant districts of Almora and Naini-Tal. Other streams of visitors returning to their homes carried the disease into the Punjab. The great fairs at Allahabad and Ballia passed off without mishap. At the latter of these, the assemblage on the great bathing day was estimated to number about half a million of people.

5. The mortality from *small-pox*, as in the case of the other chief diseases, showed a marked increase; the number of deaths rising from somewhat short of five thousand in the previous year, to upwards of twenty thousand in the year under report. The districts which suffered most severely belong to Oudh, where vaccination has hitherto been more backward than in the other divisions of these provinces. The returns show the number of persons vaccinated during the year under report to be nearly the same as that recorded in the previous year. The percentage of successful cases was, likewise, practically the same for both years. Commenting on the Notes on Vaccination submitted by the Sanitary Commissioner, the Government consider that, in view of the prevalence of plague, with the consequent suspicion and distrust on the part of the people, the results of the year must be regarded as satisfactory.

6. The mortality from plague was more than double that attributed to it in the previous year, the number of deaths rising to 84,499. The history of the epidemic does not, however, throw fresh light on the mode in which the disease is propagated, nor on the most effectual means of arresting its progress. A striking feature of the returns of plague mortality is the disproportion in the number of deaths caused by it in towns as compared with the country. The deaths from plague in towns yielded a ratio of 7·37 per thousand of population, as compared with 1·34 in rural areas.

7. The mortality from *fever*, *dysentery*, and *diarrhœa*, shows a considerable increase over that recorded in the previous year. Attempts have been made by civil surgeons in many localities to encourage the destruction of mosquitos and their larvæ by the addition of kerosine oil to pools of water; but with the object of combating malaria, attention has been mainly directed to the improvement of surface drainage and to affording the poorer classes greater facilities for obtaining quinine, measures, the value of which has been established beyond possibility of doubt by years of observation and experience.

8. *Sanitary Works.*—The Report of the Provincial Sanitary Engineer, which follows that of the Sanitary Commissioner, deals chiefly with the working of the water-pumping machinery of the six chief cities of the plains and of the hill sanitoria of Naini-Tal and Mussoorie. Now that the most populous towns of the province have been successfully provided with waterworks, the question of making a similar provision in the case of some of the other populous towns cannot remain long in abeyance. Of such towns there are more than a dozen with populations ranging from forty thousand to upwards of a hundred thousand, several of them favourably situated for obtaining water from the rivers on the banks of which they stand. Drainage schemes for some of these towns have already been considered and approved by the Sanitary Engineer. Experience shows that the introduction of a water supply into a town may be of doubtful benefit to the health of the inhabitants unless means are at the same time provided for the removal of the water when it has served its uses. Quoting from the Government review of the Sanitary Report:—
"The fact that the projects for improving the sanitary condition of municipalities approved "by the Sanitary Board amounts to Rs. 12,64,904, or 75 per cent. more than the corresponding "figures in 1901, is one indication of the vigour with which sanitary improvement is now being "pursued in all the important towns."

3rd June, 1905.

No. 4.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of the Punjab for 1903.

The first two months of the year were more than ordinarily fine and dry, the rainfall being generally in defect, and high temperatures prevailing towards the end of February. Unsettled and cooler weather followed in March and continued until June, which was drier and hotter than normal. The rains were, on the whole, lighter than ordinary over the Punjab in July and August, and heavier during September, the monsoon ceasing on the 19th of the latter month. A few slight showers fell in October, but during this and the following two months the weather continued fine until towards the end of December, when rain fell in the plains and heavy snow in the hills. The season thus appears to have been approximately normal, and, as might have been expected, the food grains at the principal markets remained steady, the rates being moderate, and, on the whole, rather lower than those of the preceding year. The rates of wages were practically the same as in 1902. As regards climate, rates of food and wages, the conditions do not, therefore, appear to have been unfavourable to the public health; but owing chiefly to the destructive epidemic of plague and great mortality from fever in some districts, the abnormally high death-rate of 49·0 per thousand of population was recorded.

2. The *birth-rate* was 42·9 per thousand of population or only a fraction less than that recorded for the preceding year. One would expect to find a marked decrease in the birth-rate recorded in the districts which suffered most severely from plague; but of the four with the highest plague mortality rates, varying from 24·27 in Lahore to 65·72 in Gujránwála, only one returned a birth-rate below the provincial average, and in the case of that one the rate was 42·6, or almost the same as the provincial rate. The district of Ludhiána lost from plague 71 out of every thousand of its population in the preceding year; yet in the year under report its birth-rate was 42·7, or almost the same as the provincial rate of 42·9. But all parts of a district affected by plague did not suffer alike; and the Sanitary Commissioner shows that in those circles which suffered most severely the number of births underwent a marked decrease. The

urban birth-rate recorded was four per thousand less than that recorded in the rural circles, including minor towns. The Sanitary Commissioner appears to think this may be due to defective registration, and proposes to have the point cleared up by special scrutiny of the birth and death registers in the principal towns. The return of a lower birth-rate in towns is not peculiar to the Punjab. In the United Provinces the birth-rate recorded in municipal towns was 42·88 as compared with the provincial rate of 46·13, whilst in Bengal the town birth-rate was only 23·74 as compared with the provincial rate of 39·00. Yet it might be expected that the agencies available for the registration of vital statistics in towns would be more efficient than those in rural circles. The proportion of male to female births registered in the Punjab was 110·3 of the former to every 100 of the latter. In the contiguous United Provinces the proportion was 107·5, and in Bengal 104·5 male to every 100 female births. Assuming registration to be equally efficient in all three provinces, the proportion of males to females born is thus shown to increase in passing from the south-east to the north-west of India.

3. The *death-rate* of 49·0 per thousand of population was the highest recorded by any province of India. It was in excess of that of the preceding year by 4·9, and of that of the five-year period 1898-1902 by 12·3. Fever and plague together were accountable for 35·5 of the total provincial death-rate of 49·0. The mortality of municipal towns was 52·89 per thousand of population, or 4·31 higher than that recorded in rural areas. Seeing that these towns recorded a lower birth-rate than rural areas, they might have been expected to record a lower, instead of a higher, death-rate than the latter. In reviewing the Sanitary Report, the Lieutenant-Governor thinks that, in the view of the fact that the incidence of plague in towns is reported to be considerably less than in rural areas, these figures seem to merit careful examination, and wishes that there were satisfactory evidence available to show that both in urban and rural areas the suggestive figures for fever and respiratory diseases are not due to the reporting of plague deaths under other names. A reference to the vital statistics of years prior to the epidemic prevalence of plague in the Punjab shows that the relative mortality in urban and rural areas in those years was practically the same as in the year under report, when plague accounted for 205,462 deaths. Taking, for example, 1895, the year immediately preceding the occurrence in Bombay of the first cases of plague which have led up to the present epidemic, it will be seen from the returns that the birth-rate of rural areas in the Punjab exceeded those of town circles by 4·3 per thousand of population; and that the death-rate of town circles at the same time exceeded those of rural circles by 4·9. During the year under report, the birth-rate of the 42 largest towns was less than that of rural circles by 4·0; and the death-rate higher by 4·3 per thousand of population. It would thus appear that the relation which the birth and death-rates of towns have to those of rural areas in the Punjab were approximately the same during the years before plague appeared as during those in which it prevailed in epidemic form. It is probable, however, that some of the deaths due to plague may have been registered under the head of fever or of respiratory diseases both in towns and in rural areas. Ample evidence will be found in the reports of the Health Officers of Bombay and Calcutta in support of the probability of many deaths having been hitherto ascribed to fevers, which were really due to plague. It can readily be understood that, during the period when drastic official measures were being adopted with the object of stamping out plague, some people would endeavour to evade these; concealing, or reporting as due to other causes, cases suffering or dying from plague; but now that these measures have been discontinued the people should have less inducement to submit false reports of the causes of illness or death. Moreover, it is not always easy, even for medical officers, to distinguish between certain obscure cases of plague and some kinds of fever, such as those of the remittent and relapsing types. Death due to plague might, therefore, not unfrequently be attributed to fevers by mistake rather than by design. The death-rates among infants under one year of age were considerably higher than those recorded in the preceding year. For male children this rate was 260, and for female children 270 of every thousand born; whilst in 1902 the corresponding ratios were only 233 and 241. These figures may be taken as some measure of the comparative healthiness of the two years. The proportion which the deaths of male children bear to the deaths of female children in the Punjab is worthy of note. In other provinces, the United Provinces and Bengal, for example, the death-rate amongst male infants is considerably higher than the death-rate among female infants; in the Punjab the reverse is the case, the death-rate among female infants being considerably higher than the death-rate among male infants.

4. Of the *chief diseases, cholera,* which had been in almost complete abeyance during the two preceding years, again prevailed in epidemic form and was accountable for 14,688 deaths. Two isolated and imported cases were reported in Delhi during the first week in April; but it was not until after the disease broke out at the Great Fair at Hardwar about the 13th of the month that the disease became diffused over the Punjab. During April cases occurred in 15 districts of the province, and in one of these districts the first case is said to have been that of a pilgrim returning from the Hardwar Fair. During the following three months the disease steadily increased, reaching its climax of severity in July, and declining in the following months until, in December, only two deaths were credited to it. Compared with the mortality from cholera following previous Kumbh Fairs at Hardwar, that recorded during the year under report was small, and this favourable result, the Lieutenant-Governor says, "appears to have been largely "due to the prompt and effective measures adopted by the district staffs of the Province to cope "with and obviate a spread of the disease."

5. The mortality from *small-pox* showed a further increase during the year under report, rising to 0·78 from 0·55 per thousand of population, in the previous year, and from an average of only 0·34 recorded for the previous five years. During recent years of plague prevalence in the Punjab, vaccination has had many difficulties to contend against; but, in spite of these, the returns show a considerable increase in the total number of vaccinations during the year under report as compared with the numbers recorded in either of the two preceding years. Of

the total of 581,221 successful primary vaccinations, as many as 472,669 were performed on children under one year of age. The attention paid to the protection of infants continues to be a satisfactory feature of vaccination in the Punjab, although the number successfully operated on still falls far short of the number available for vaccination. Deducting the 228,673 deaths of infants under one year of age from the 862,862 births recorded during the calendar year 1903, there remained 634,189 available for vaccination; of these 472,669 were successfully operated on, leaving 161,520 unprotected against small-pox. The accumulation year by year of so large an unvaccinated residuum would, obviously, supply abundant material for the propagation of small-pox in seasons favourable to the epidemic prevalence of the disease.

6. The province again suffered from a severe epidemic of *plague*, no fewer than 205,462 deaths having been recorded under this head. And it is very probable, as suggested in the Government review of the Sanitary Report, that the recorded number falls short of the actual number, not a few deaths due to plague, in some of its obscure forms, having probably been reported under the heads of fever or respiratory diseases. As in the previous year, the disease caused enormous loss of life in some districts whilst it passed lightly over others. In 1902 the Ludhiána district lost 71 out of every 1,000 of its population from plague alone; this year the same district lost only 12·3 per thousand of its population from that disease. On the other hand, Gujránwála, in which the mortality had been comparatively light in the previous year, suffered ten times more severely in the year under report, losing 63·0 per thousand of its population from plague. The disease reached its maximum intensity in April, during which 113,074 deaths were ascribed to it, and its minimum in August, when the number of deaths fell to only 111. From August until the end of the year the disease again slowly increased in prevalence, the deaths reported as due to it in December having been 8,416. In dealing with plague, the element of compulsion has almost entirely been eliminated; and "while Government has recognised and "provided for the obligation of rendering assistance to the inhabitants of plague-stricken towns "and villages, it has left the choice of adopting or neglecting precautionary measures almost "entirely to the people themselves." The people are still freely offered anti-plague inoculation. It is stated that during the year 325,550 inoculations were performed in the province, and that, although the results varied in different areas, taking the figures for the Province as a whole, the liability of the uninoculated to death from plague was two-and-a-half times greater than the liability of the inoculated. Although there are occasional signs that the people are awakening to a sense of the need for adopting energetic measures for combating the disease, they are said still to regard its ravages mostly with apathy.

7. The mortality due to *fever* was somewhat higher than the mean ratio for the previous five years. In the districts which suffered most, unusually heavy rainfall, in some cases accompanied by wide-spread inundations, is assigned as the cause of the excessive prevalence of the disease. The Civil Surgeon of Muzaffargarh, in which a fever death-rate of 29·7 was recorded, writes that there were "unusually heavy floods throughout the district, so much so that the "greater part of the district remained under water for several months afterwards, and as a "consequence a most severe epidemic of malarial fevers burst out after the floods." Under the conditions described, measures for the destruction of mosquitos would have to be conducted on a somewhat extensive scale to produce much result. Where such measures were tried during the year, as in the Gujránwála and Gujrát districts, their application was interfered with by the severe prevalence of plague.

8. The provincial death-rate of 0·82, recorded as due to *dysentery and diarrhœa*, was the same as in the previous year. Such a rate probably represents but a small fraction of the actual rate. These diseases would appear to be more prevalent, perhaps because better recognised, in towns than in rural circles. The death-rate per thousand of population ascribed to them in towns was 2·38, and in rural circles 0·65. Likewise, as regards the number of deaths registered under the heading of *respiratory diseases*, the wide divergence between the ratios in some districts as compared with neighbouring districts leads to the belief that this may, in part at least, be due to differences in the diagnosis of these diseases rather than to inequality of their incidence.

9. Of the *Sanitary Works* carried out during the year, perhaps none were of more importance than those having for their object the improvement and protection of the water supply. No fewer than 8,825 wells were cleaned out and 2,710 protected by parapet walls. Individually, these may be regarded as minor works; but collectively they are of vast importance and cannot but exercise a marked influence on the public health. The endeavour to stimulate village communities to take an interest in the sanitary improvement of their villages by the offer of rewards to those who can show the best results does not appear, as yet, to have met with much success. The Report of the Sanitary Engineer to Government, given as an Appendix to the Report of the Sanitary Commissioner, deals, amongst other questions, with the scheme for the biological treatment of sewage. It is evident from the Report that serious difficulties have been met with in the practical working of this method of sewage treatment; but the Engineer finds himself in a position to say that "septic tanks have given good results, so far." Special efforts have been made to encourage the use of sewage at outfalls for land irrigation. Owing to the inertia of municipalities, marked progress in this direction cannot yet be recorded; but experience in most parts of the world having proved this method of sewage disposal to be sound in principle and generally profitable from a practicable point of view, the efforts made to induce the people to adopt it may, if persevered in, reasonably be expected to prove ultimately successful.

3rd June, 1905.

No. 5.

MEMORANDUM by the ARMY SANITARY COMMISSION on the REPORT on the SANITARY ADMINISTRATION of the NORTH-WEST FRONTIER PROVINCE for the year 1903.

Measured by its death-rate, the year was less healthy than its predecessor. The rainfall of 12 inches, recorded at the registering stations of Peshawar and Dera Ismail Khan, was much greater than in the previous very dry year, when only 3·9 inches fell at the former and 6·9 at the latter. The harvests were, on the whole, good, and the prices of food cheaper than in the previous year, whilst the rate of wages remained practically the same.

2. Accompanying increased mortality, the *birth-rate* fell to 31·6 per thousand of population from 33·6 recorded in the preceding year. The falling-off was mainly due to the decrease in the number of female births. In the Province as a whole, for every 122·8 births of male children there were only 100 of female children registered. In Peshawar, the most populous district of the Province, the proportion of male to female births recorded was 136 of the former to 100 of the latter. The question of the wide divergence between the number of male as compared with the number of female births annually registered has been engaging the attention of the Chief Commissioner, who suggests that a special effort should be made to secure an exact record of the births in a selected area. This suggestion is being acted upon, and the Sanitary Commissioner promises a report on the result next year. The inquiry will, doubtless, be useful, and may throw light on other abnormal features of the returns of the vital statistics of this Province and of the Punjab, from which it has only recently been detached. In all the other provinces of India the death-rate recorded for male children under one year of age is considerably higher than the death-rate for female children of the same age. This is in accordance with what is generally regarded as a natural law. In England and Wales, according to Farr's Tables, the annual rate of mortality per thousand male children under one year of age is 205·1, and per thousand female children of the same age 154·4. In India the mortality amongst female infants approximates much more closely that amongst male infants; and in one province, the Punjab, the death-rate amongst female infants per thousand born actually exceeds the death-rate amongst male children of the same age. In the North-West Frontier Province the death-rate recorded is nearly the same amongst the infants of both sexes, being for the year under review 202·9 for males and 198·8 for females. The higher proportionate death-rate amongst female infants in India, as compared with that prevailing in England, may not be without its significance in a country in which the birth of a female child is not usually regarded as a subject for congratulation or rejoicing. In the Punjab, where the natural law, in accordance with which the rate of mortality is higher amongst male than amongst female infants, is reversed, the causes which lead to such a result seem to be deserving of investigation.

3. The rise of the *death-rate* from 24·4 in the previous year to 28·4 in the year under review was chiefly due to increased mortality from fever, small-pox, and cholera. The increased death-rate from *fever* may have been connected with the increased rainfall of the year, although Kohat, the district which recorded the highest death-rate of 26·96 per thousand of its population in the previous exceptionally dry year, records the slightly lower rate of 26·59 in the comparatively wet year under report.

4. *Small-pox* was much more fatal than in the preceding year, and was the cause of 2,694 deaths, or a death-rate of 1·35 per thousand of population, as compared with 0·54 in the previous year. In connection with the question of the abnormal number of births of male children as compared with those of female children in the Peshawar District, in which 136 of the former were registered against every 100 of the latter, it may be noted that, whilst the deaths from small-pox of males in that district numbered 896, those of females numbered 899. Vaccination made good progress in the Province during the year, the total number of operations increasing by 9·8 per cent. over the number recorded for the previous year. The increase was entirely in primary vaccination, re-vaccination showing a large decrease. The successful vaccinations were at the rate of 43·10 per thousand of the population of the province, or largely in excess of the recorded birth-rate of 31·6 for the calendar year 1903. The percentage of 91·52 successful cases in primary vaccination was not high; a result which appears to have been, to some extent, due to the low ratio of success yielded by vaseline lymph. Animal lymph was employed in the majority of cases, and yielded a percentage of 93·14 successful cases; vaseline lymph gave a percentage of success of only 79·86 in the 12,400 cases in which it was used; whilst human lymph gave better results than either of the other kinds of lymph employed, yielding a percentage of 96·73 successful cases. "Excellent work was done in Chitral, where no less than "28,353 vaccinations were performed." The ready acceptance of vaccination in this remote frontier state, into which it has only recently been introduced, is in striking contrast with the slow progress made by it in other provinces of India, where it has had to make its way against passive resistance, or open hostility of a superstitious and suspicious population.

5. *Cholera,* from which the Province was entirely free in the previous year, was accountable for 1,354 deaths during the year under report. The first cases of the disease in all the affected districts were clearly traceable, it is said, to importation. In the earlier months the importation was from Hardwar, where a severe outbreak occurred at the time the Great Fair held at that place was breaking up in the middle of April.

6. Little reliance can be placed on the returns of deaths ascribed to *bowel complaints* and to *respiratory diseases*. The death-rates of only 0·28 recorded as due to the former, and of 0·5 to the latter per thousand of the population probably represent but a fraction of the actual rates. The returns of sickness and mortality for the Native Army show the high death-rates

caused by respiratory diseases amongst the troops stationed in the North-West Frontier Provinces. To quote only a few examples: the Peshawar Native Garrison recorded, from these diseases in 1903, a death-rate of 1·54 per thousand of its average strength; that of Mardan 5·2; that of Kohat 6·08; and that of Dera Ismail Khan of 12·28. Moreover, in any comparison between the mortality amongst the troops and the general population, it has to be kept in view that the former are selected men, of sound constitution, in the prime of life and living under carefully supervised hygienic conditions; whilst the latter are of all ages from infancy to extreme old age and living under conditions less favourable to health and recovery from sickness. It may be presumed, therefore, that the high death-rate due to respiratory diseases amongst the Native troops stationed in the province is not lower amongst the general population.

7. The record of *sanitary works* executed during the year, although it does not include any of magnitude, shows that active measures are everywhere in progress to provide the population with pure water-supplies. In Peshawar, the largest town of the Province, upwards of thirteen thousand rupees were expended on extension of the water-supply, cleaning wells and maintenance of the water-works establishment; whilst in Dera Ismail Khan, the next most populous town, "all the drinking-water wells were cleaned." In the other towns of the Province, none of which has a population of twenty thousand, improvements in their water supplies and drainage were carried out as far as funds were available. Much useful sanitary inspection work was carried out by the Civil Surgeons, who, whilst on tour, visited and reported upon the sanitary condition of many towns and villages in their districts.

3rd June, 1905.

No. 6.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Burma for 1903.

A summary is given of the chief climatic conditions of the year, together with an estimate of the influence which these are believed to have exercised on the public health. The rainfall and humidity were above the normal; the former averaging in Lower Burma 151·4 inches, as compared with 125·70 in the preceding year, and with 133·58, the mean of the previous five years. Accompanying this exceptionally heavy rainfall, the maximum temperature was below, and the minimum above, the maximum and minimum recorded in the previous year. The price of the staple food grain of Lower Burma, which is rice and rice only, was higher than in 1902, and also higher than the average for the previous five years. "Prices were highest in August, "September, and October, when sickness and mortality were also at the maximum." But this rise, the Sanitary Commissioner adds, was nowhere so great in the Lower Province as to affect either reproduction or mortality. The lot of the people of Burma would appear to be anything but a hard one. "The people everywhere in the plains are well-off, food is plentiful, and the "Burman takes life easily, and, as a rule, employs Indian labour at a high rate of wages to "harvest his crop." Nearly the same description is given of the conditions of life in the neighbouring province of Assam. In both provinces, fecundity and mortality are said to be unaffected in ordinary seasons by prices of food or rates of wages. The character of the rainfall is believed, however, to have an important influence on the public health. The Sanitary Commissioner thinks it may be generally accepted that a normal monsoon produces a healthy year, and an abnormal one, in which the rainfall is excessive, an unhealthy year. To the climatic conditions accompanying the exceptionally heavy rainfall, the increased mortality of the year under report is ascribed.

2. In reviewing the Report, the Lieutenant-Governor comments on the slow progress made by the scheme for improving the registration of vital statistics. Complete returns of births and deaths are still available only for Lower Burma. In Upper Burma, which was annexed in 1886, the registration of births is limited to towns with an aggregate population of less than 300,000; but registration of deaths is now in force both in towns and in rural areas. The birth and death-rates recorded for both Upper and Lower Burma do not as yet probably furnish even an approximate measure of the actual fecundity and mortality. In a province, the population of which increased by 24 per cent. during the last ten-year intercensal period, the birth-rate of 33·54, for the year under report, is probably much below the actual rate, whilst a death-rate of only 24·13 recorded for a year, acknowledged to have been unhealthy, is probably no less understated. As regards Upper Burma, registration has made little more than a beginning. In the few towns to which the registration of births is still confined, the birth-rate of 37·48 recorded for them shows that satisfactory progress is being made; but the death-rate of 21·80, returned for the whole of Upper Burma, is of use, mostly, as indicating how much will have to be done to improve registration before reliable deductions can be drawn from the vital statistics obtained from that part of the province. Meanwhile, the Government, while acknowledging the difficulty of arranging the details in connection with the scheme for improving the system of registering vital statistics, considers it important that it "should be completed without further "delay." It is stated that, of the 28,530 towns and villages under registration in the province, 14 781, or 51·8 per cent., are shown as having had their records tested. The method adopted for such testing is not described; but, in not a few of the cases, it is probable that it was of a somewhat perfunctory nature. A house-to-house inquiry for the purpose of ascertaining the occurrence of births and deaths in a town or village is a laborious proceeding, requiring much

time and patience; but if the registers are to be subjected to a thorough test, no other method is known to be effectual. The character of the so-called testing adopted by the inspecting agencies may perhaps be inferred from the following statement: "Of the registers tested by district "officials, 0·63 were found defective. A civil officer's examination of these registers usually "only extends to the signing of the records and to the detection of clerical errors, which give "no proper idea as to the accuracy or otherwise of registration."

3. From most of the *Chief Diseases* there was increased mortality during the year under report as compared with its predecessor. *Cholera* was much more prevalent and fatal during 1903 than in the previous year—the deaths attributed to it in Lower Burma numbering 5,346 as compared with 1,844 in 1902. The deaths registered from the disease in Upper Burma numbered 2,887, but in the present backward state of registration little reliance can be placed on these figures. Of the cause, or causes, which led to this increased cholera mortality in the year under report, no explanation is attempted.

4. Of the chief diseases, *small-pox* was the only one which was less fatal than in the previous year. The ratio of deaths per thousand of population due to it was only ·23 as compared with ·72, the mean for the previous five years. The number of vaccinations performed shows an increase of 27,791 primary operations, and of 333 re-vaccinations. The percentage of success in cases of primary vaccination was only 87·20, whilst in re-vaccination it was 54·97. In paragraph 6 of the "Notes and Statistics on Vaccination in Burma for 1903-04," we read: "In the town of Rangoon 65 per cent. of the available children were protected. In this town "there was an increase of 4,632 operations, or 54 per cent. over last year's work, and over "100 per cent. on the work of 1901-02. The ratio of success was 98 per cent." This favourable account does not appear to be in complete agreement with the figures of Statement No. I. in the Appendix. In the Statement referred to, the percentage of success in primary vaccination, excluding the unknown cases, is recorded to be only 94·60, and in re-vaccination 70·96. Moreover, the total primary vaccinations number only 4,879, and of these the result was not ascertained in no fewer than 2,046 of the cases. By far the larger proportion of the season's operations consisted of re-vaccinations, these numbering 8,470; whilst the result in more than one-half of them, 4,507, was not ascertained. These discrepancies are probably due to the figures, given in the paragraph from which quotation has been made, having reference to Rangoon town as distinct from the district of the same name; but on the margin, against the paragraph in question, Appendices A and C are referred to in support of the statements therein set forth. Vaccination in Burma has much to contend against. There is said to be a strong prejudice in favour of inoculation in the districts generally; whilst the establishment employed to overcome this, and to popularize vaccination, is described as "badly educated, badly paid, and badly "disciplined." The Sanitary Commissioner truly says, efficient supervision is essential, "and "is the one indispensable condition to the successful working of the Vaccination Department." The low percentage of 87·20 successful cases in primary operations shows that there is room for improvement in the quality of the vaccine lymph employed.

5. The measures adopted by the Government for the protection of the province against *plague* have proved completely successful. Although ten imported cases were detected in the towns of Rangoon and Moulmein during the year, from none of these is the disease known to have extended to any one of the indigenous inhabitants. As observed in the Government resolution on the Sanitary Report, "This satisfactory result amply justifies the strict enforcement of the "preventive regulations."

6. The mortality due to *fever*, which the Sanitary Commissioner describes as "the great "death cause of the province," increased from a ratio of 8·86 per thousand in the previous year to 10·14 in the year under report, and was almost exactly the same as the mean of the previous five years. The death-rate attributed to fever in Lower Burma is less than that recorded for any other Indian province, excepting Madras. This might be supposed to be a result of the defective state of registration in Madras and Burma; but an examination of the returns submitted by the jails, the records of sickness and mortality in which are above suspicion, shows the death-rate among the prisoners to be in agreement with that recorded for the free population of the two provinces. This will be apparent from the statistics of the general population, given in Appendix B to Section VI of the Annual Report of the Sanitary Commissioner with the Government of India for 1902, and from those of prisoners given in Table XL of that Report. The cause of the increase in the prevalence of fever during the year under report is, no doubt, rightly attributed by the Sanitary Commissioner in main part to "the enhanced rainfall and "consequent greater humidity of the atmosphere, the more extended water-logging of the soil, "and the increased rain water lodgments on the surface." For the prevention of fever, no systematic measures were carried out for the destruction of mosquitos; but municipalities employed their conservancy establishments in filling pits and draining unnecessary collections of water. Increased facilities were also afforded the people throughout the province for the purchase of quinine.

7. The death-rate of 1·61 per thousand of population from *dysentery and diarrhœa* in Lower Burma shows some increase over that recorded for the previous year, but is slightly below the mean of the previous five years. As in the case of fevers, the annual variation in the mortality ascribed to bowel complaints appears to be influenced by the climatic conditions of the seasons, the effect of such conditions being intensified, or diminished, by the character of the sanitary environment.

8. The death-rate credited to *respiratory diseases* during the year was only ·35 per thousand of population. Such figures, it is needless to observe, can represent but a small fraction of the actual mortality due to these affections. In the case, alike of bowel complaints and respiratory diseases, the mortality attributed to them is probably much understated in the returns.

9. The *sanitary works* which absorbed the greater proportion of the municipal funds expended on sanitation were those connected with the provision of pure water supplies. The new Hlawga water-supply scheme for Rangoon was approaching completion. By replacing the supply from the Royal Lakes, which for years has been condemned as unfit for drinking purposes, the new supply is expected to do much to improve the health of the town. The waterworks for Moulmein and Prome are also in course of completion. Of the large and important city of Mandalay with its 183,816 inhabitants, the supply has long been pronounced to be objectionable, and the need for replacing it by an adequate and pure supply declared to be urgent. With the latter object in view, projects have been prepared; but none of them appears, so far, to have been taken in hand. The latest proposal is to obtain the new supply from artesian wells. Regarding this, the Sanitary Commissioner writes: "Should it, however, be decided to supply the town from "artesian wells, the liability of their pollution from surface water should not be lost sight of, "as the town of Mandalay is riddled throughout with cess-pits or well privies." The conservancy and drainage of Mandalay, also, continues to be unsatisfactory, the municipality objecting to any efficient scheme for their improvement which would involve additional taxation. "Whatever scheme may have been decided upon," writes the Sanitary Commissioner, "I would "suggest for the consideration of the Committee the adoption of the septic tank system for the "ultimate disposal of the night-soil." Under suitable conditions, and expert management, the septic tank system has, no doubt, been found to yield good results; but experience in India, as exemplified by the trials conducted under the direction of the Sanitary Engineer to the Punjab Government, shows that such results are by no means so easy of attainment as some of the accounts given of this method of sewage treatment might lead those adopting it to expect.

3rd June, 1905.

No. 7.

Memorandum by the Army Sanitary Commission on the Sanitary Report of the Central Provinces and Berar for 1903.

Hitherto separate Sanitary Reports have been submitted for the Central Provinces and for the Commissionership of Berar; but now that the latter has been absorbed by the former, one Sanitary Report suffices for both. By the annexation of Berar, the population of the Central Provinces, which was previously 9,770,567, has been raised to 12,491,909.

2. Judged by its vital statistics, the year was less healthy than the preceding one. The birth-rate decreased, whilst the death-rate increased. Of the meteorological features of the year little mention is made in the Report; but in the review of it by the Chief Commissioner it is stated, that "the character of the monsoon, which was extraordinarily heavy, caused fever to be "more prevalent among all classes." Had it not been for the severe epidemic of plague, however, which caused in the Central Provinces and Berar combined a death-rate of 4·13 per thousand of population, the Chief Commissioner thinks the year might have had some claim to be reckoned a fairly healthy one.

3. The *birth-rate* of the Central Provinces, which had been 48·29 in the previous year, decreased to 44·27; but was still the highest recorded, excepting in 1902, during the past 20 years. In Berar the decrease was more marked; the birth-rate, which was 56·9 in 1902, falling to 48·16 in the year under review. For the Central Provinces and Berar combined, the year's birth-rate was 45·11 per thousand of population; and was higher than that recorded by any other Indian province, excepting the United Provinces of Agra and Oudh. The rural continues to be considerably higher than the urban birth-rate. The birth-rate of towns for the year under report may, to some extent, have been lowered owing to the flight of a portion of their inhabitants, consequent on the plague scare; but, as the Sanitary Commissioner remarks, "doubtless the "village woman will always be more prolific than her urban sister."

4. The *death-rate* of the Central Provinces, which had been 25·82 per thousand of population in the preceding year, rose to 33·79 in the year under report, and somewhat exceeded the decennial mean of 32·44. To this large increase of mortality, plague and fever were the chief contributors; and the former of these two diseases is believed by the Sanitary Commissioner to have been the cause of a greater number of deaths than the returns would indicate. In Berar, which suffered far more severely from plague than the adjoining Central Provinces, the death-rate rose to 41·74 from 32·80 in the previous year, and from 35·3, the decennial mean. Apart, however, from the effect produced by epidemic disease, there can be no doubt that the unusually high birth-rates of the year under report and of its predecessor must likewise have had a share in raising the death-rate. When it is seen from the returns, that 563,548 children were added to the population during 1903, and that these died at the rate of 271·37 per thousand, as compared with the recorded death-rate of 35·52 at all ages, the effect of the high birth-rate in raising the provincial death-rate will be obvious. The districts which recorded the highest plague mortality were also, generally, those which recorded the highest death-rates among children under one year of age. "The conclusion is inevitable," writes the Sanitary Commissioner, "that many infants "died from plague, or from exposure and malnutrition consequent on it. Many no doubt lost "their mothers from plague, and that in most cases was probably an equivalent to a sentence "of death." The death-rate in the towns of the Central Provinces was more than double that in rural circles. In the preceding year the urban death-rate was 32·42, and in the year under report 66·33 per thousand of population. "The enormous relative increase in the urban death-"rates is due to plague."

5. Registration of vital statistics continues to receive much attention. The accounts given of the results of the checking of entries of births and deaths by Native Superintendents of Vaccination would lead to the conclusion, either that the record of vital statistics by Kotwars, or village watchmen, is extraordinarily accurate, or that the check to which the record has been subjected by the inspecting officers has not been very stringent. In paragraph 24 of the Sanitary Report, it is stated that the Police had recorded 50,267 births and 35,474 deaths, doubtless reported to them by the Kotwars. The Native Superintendents of Vaccination, in verifying these births and deaths, found that, of the former only 272 had been omitted, and 30 of the latter. In the district of Balaghat "not a single error was detected." On the other hand, Civil Surgeons tested 25,023 entries in the Kotwars' books and detected 383 omissions. The contrast between the number of omissions detected by the Native Superintendents and the number detected by the Civil Surgeons is striking. The former, in verifying a total of 85,983 births and deaths, find only 302 omissions; the latter, in verifying a total of 25,023, find 383 omissions. The number of omissions detected would thus seem to vary with the agents employed in checking the entries, and cannot, therefore, be accepted as a reliable measure of the accuracy, or inaccuracy, of the registration of vital statistics in the province.

6. Of the chief diseases, *cholera*, though somewhat more prevalent than in the preceding year, had only 437 deaths attributed to it. *Small-pox* was much less fatal than in 1902, but yet accounted for upwards of two thousand deaths in the Central Provinces. In reviewing the Sanitary Report, the Chief Commissioner is struck by the remarkably small number of deaths from small-pox in Berar. If the progress of vaccination in Berar is traced during the past 35 years, the cause of this remarkable immunity of its population from small-pox becomes clear. It is due to the efficiency of its Vaccination Department, which has succeeded in effecting a steady reduction in small-pox mortality from a ratio of 2·02 deaths per thousand of population, recorded for the five-year period commencing from 1868-69, to only 0·04 in the year under report. In the Central Provinces, of which Berar is now a division, the mean ratio of deaths from small-pox for the past five-year period is 0·39; and the ratio for the year under report 0·21; the latter rather more than five times greater than that recorded for Berar. As might have been expected, the widespread prevalence of plague interfered with the work of vaccination during the year under report, especially in Berar, which suffered much more severely from the epidemic than the Central Provinces. A breakdown at the depôt in which lymph is collected and prepared for distribution to the vaccinators was an additional misfortune, and is said to have retarded work for about a month. The effect of these adverse influences resulted in a decrease in the number of primary vaccinations in five of the six districts of Berar. In the Central Provinces, however, there was not only no falling-off in the number of persons vaccinated during the year, but a considerable increase both of primary operations and of re-vaccinations. Plague, which was so fatal in Berar, was much less severe in the Central Provinces, and, it may be assumed, interfered proportionately less with the progress of vaccination work. In paragraph 19 of the Notes on Vaccination, it is stated that "many of the Civil Surgeons complain of the new rule "introduced last year to inspect children at the people's own villages instead of collecting them "at a fixed centre." Colonel Moriarty's sole object in issuing such a rule was, doubtless, not confined to saving infants and their mothers from the hardship of long journeys to a collecting station, and sometimes of long and weary waiting there before the arrival of the inspecting officer, although this object is of itself of no small importance. Those who have had experience in such methods of inspecting the work of vaccinators cannot have taken long to discover that, not unfrequently, only the successful cases of vaccination, and such as would do credit to the vaccinators, are brought to the rendezvous; cases of unsuccessful, or doubtful, vaccination are left behind in their villages; and when the inspecting officer calls out the absentees' names from the register, he is likely to be told that they are sick, or have left their homes on a visit to relations. This explanation the inspecting officer has to accept for what it is worth, since, being at a distance from the absentees' village, he is unable by inquiry to check it. In testing the quality of the work of a vaccinator the inspection is thus shorn of much of its value. No doubt the collection of the children of several villages at a spot convenient for their inspection by the Civil Surgeon enables that officer to record a greater number of cases inspected at less cost of time and labour to himself than if he visited the several villages to which the children belonged; but this advantage is more than neutralized by the opportunity it affords the vaccinator of bringing forward only the cases of vaccination which he wishes to be seen, and of keeping away those which he thinks it desirable should not be seen by the Inspecting Officer. The unexpected examination of a vaccinator's work, case by case, in a single village, would more effectually test its quality than the inspection of the children collected from many villages at some spot away from their homes.

7. The epidemic of *plague* is described in considerable detail; but the account of its ravages in the districts which suffered most, although interesting, does not add materially to what is already known of the ways of the disease. Berar was the chief sufferer, and recorded a plague death-rate of 5·94 per thousand of its population, as compared with 3·61 in the rest of the province. Yet, these figures, the Sanitary Commissioner thinks, do not represent the full extent of the loss of life from plague. "There can be little doubt," he says, "that many deaths, "recorded under 'fevers' and 'other causes,' were really due to plague"; and he comes to the conclusion that the actual, exceeded the recorded, plague mortality by about 10 per cent. In his narrative, he gives instances of the spread of the disease by fugitives from plague-stricken towns and villages. The people, he says, have begun to realize that unless they protect themselves, the State can do but little for them. "They understand the value of evacuation, and, "in villages especially, frequently act on their own initiative when rats commence to die and "before human plague appears." Muhammadans suffer more from plague, it is said, only because they will not vacate infected houses and move into camp with the same freedom as others. Inoculation is not popular; and the Sanitary Commissioner fears the same must be said of chemical disinfection.

8. *Fever* is credited with a death-rate of 15·27 per thousand of population, for the entire province; the Berar division, taken separately, recording a rate of only 11·57. Seeing that Berar suffered more severely than the Central Provinces from plague, one would have expected a higher death-rate from fever, had many of the deaths due to the former disease been recorded under the head of the latter. Doubtless, as the Sanitary Commissioner believes, not a few plague deaths were attributed to fever; but now that the methods of coercion, by which it was formerly endeavoured to enforce plague measures, have been discontinued, the people can have no strong motive in reporting deaths from plague as having been due to other causes. There are some obscure forms of plague, which even medical men have difficulty in diagnosing; and it would be no matter for surprise if some of these found their way into the returns under such other headings as fever, or respiratory diseases. During the preceding year it was arranged that "systematic operations for the prevention of malaria would be carried out in five selected "municipal towns." The results of these operations have now been reported. In two of the five selected municipalities it is stated that "nothing special was done"; in a third, that "little "could be done owing to want of funds"; whilst in the remaining two, active measures were adopted with the object of filling up, or draining, hollows in which water might collect and serve as breeding places for mosquitos. The year was an unfortunate one for giving the experiment a fair trial, owing to the widespread prevalence of plague, which fully occupied the time and attention of Civil Surgeons. So far, the results of the action taken are said to have been indefinite; but it is proposed to persevere with the measures begun, and to extend them to other places.

9. In "a year of delayed and heavy rainfall following on a comparatively dry year, a "conjunction that usually leads to deterioration in the public health," it was to be expected that, as in the case of fever, there would also be an increase of mortality from *dysentery and diarrhœa*. In the Central Provinces, the death-rate attributed to these diseases was only 1·80; whilst in Berar it was 5·74 per thousand of population. Whether this greater mortality from dysentery and diarrhœa recorded in Berar is due to greater prevalence there of these diseases, or to more accurate registration of the causes of death, the Sanitary Commissioner is, at present, unable to say.

10. The returns of deaths ascribed to *respiratory diseases* are, as yet, probably almost, or altogether, without value. As pointed out in the Report, whilst in one district only two deaths are attributed to these diseases, in the next district, with a smaller population, the number is 1,960. "Anything approaching to accuracy," writes the Sanitary Commissioner, "is with our "present reporting agency, of course, impracticable; but variations such as this would seem to "depend on a difference in local instructions."

11. The *sanitary works* of importance carried out during the year were few in number; but much was done in the municipalities, as well as in villages, towards improving and protecting the drinking water supplies. A project has been prepared for the drainage of the town of Nagpur and only awaits execution by the municipality. The Report shows that considerable sums have been expended in the several districts on minor drainage works, and in the improvement of conservancy arrangements.

3rd June, 1905.

No. 8.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Assam for 1903.

1. In the second paragraph of the Report a useful account is given of the general meteorological features of the year. Without its being assumed that they stand to each other in the relation of cause and effect, the climatic conditions, prevailing prices of food and rates of wages are recorded side by side with the death-rates, leaving for inference the influence which the former may have had on the latter. Regarding the season's rainfall, it is stated that there was a reduction of this in all the districts dealt with in the tables of the Report. "In most districts the rainfall is noted as having been seasonable and regularly distributed." Accompanying these conditions, "the general death-rate of Assam was lowered, as were the "rates from cholera, small-pox, fevers, and bowel complaints."

2. The *birth-rate* recorded for the province was 35·57 per thousand of population, as compared with 34·21 in the preceding year. In the district of Darrang only was the birth-rate exceeded by the death-rate; and this was due not so much to a low birth-rate in that district as to an exceptionally high death-rate. The birth-rate of Darrang was 35·26, or almost the same as the provincial rate; but its death-rate was 38·10 as compared with a provincial rate of 26·55. It is noted that this was the district in which kálá-ázár was most prevalent and malignant in 1903. The recorded proportion of births of male to births of female children was 106·72 of the former to 100 of the latter. In the Surma Valley, the climatic conditions of which are practically the same as those of Lower Bengal, the proportion of male to female children born was 105·94, or not widely different from the proportion of 105·4 of the former to 100 of the latter recorded for the province of Bengal. Wide divergence between the proportion of male to female births may usually be taken to indicate defective registration. A reference to Annual Form No. I. of the Appendix shows that, of the three districts which record ratios of male births much in excess of the provincial average, two return low birth-rates of 27·81 and

of 28·04 respectively, rates so much below the standard of 45 laid down for the province, as scarcely to be capable of explanation except on the assumption that a large number of births escaped registration.

3. The *death-rate* of 26·55 for the year under report compares favourably with the previous year's rate of 29·01, and with the rate of 33·90 for the five-year period 1897-1901. In the three districts in which births and deaths are registered by paid village watchmen, the death-rates recorded are higher than those recorded in the other five districts, excepting in the case of Darrang. This is probably equivalent to saying that fewer deaths are omitted from the returns made by the paid village watchmen than from those made by the, hitherto, unpaid village headmen. "The high death-rate of Darrang, 38·22, is probably due to kálá-ázár." Seeing that this is one of the districts in which registration is left to unpaid village headmen, it may be assumed that its death-rate, although higher than that of any other district of the province, is yet understated. As observed, however, in the Government review of the Report, Darrang records an increased birth-rate as well as a high death-rate; and this may be taken to indicate improved registration. With a view to giving him a motive for the better performance of his duties of registrar of births and deaths, the Government has arranged to remunerate the hitherto unpaid *gaonbura*, or village headman, for his services. This measure may be expected to have the effect of improving registration in the five districts in which men of this class are employed up to the level, not a very high one, reached by the remaining three districts of the province. The following remarks, quoted from the Government review of the Sanitary Report, indicate the close attention which is being given to the subject of vital statistics, and the strenuous efforts being made to improve their registration. After commenting on the defective state of registration in certain municipal towns, the Government Resolution continues: "The work has "evidently been grossly neglected in Silchar, where, for the second year in succession, there "was no prosecution for failure to report vital occurrences, although special attention was drawn "to the matter in the Chief Commissioner's Resolution on the Sanitary Report for 1902."

4. From all of the *Chief Diseases* there was diminished mortality during the year under report as compared with 1902. *Cholera* was credited with a mortality of 1·58 per thousand of population, as compared with 2·40 in the previous year, and with 3·66 for the decennium 1891-1900. In one district only was the mortality excessive; and in this, the district of Nowgong, the death-rate ascribed to it was 6·61 per thousand of population. The coolies of the tea gardens in the Nowgong district suffered far less than the general population. "The comparative "immunity of the tea gardens in the Nowgong district," writes the Sanitary Commissioner, "is attributed by the Civil Surgeon to the fact that all the gardens except two are remote from "the river Kallang, to the banks of which the disease was for the most part confined; and to "the adoption by the garden managers of early and active measures of sanitation and prevention, "including in some cases the permanganating of the wells." Half the total of 22 deaths from cholera, in the 35 tea gardens liable to inspection in the Nowgong district, are stated to have occurred in the two gardens which are near the Kallang. The death-rate from cholera among immigrant tea-garden coolies was lower than for any other year on record, except the years 1902, 1893, and 1890. "The occurrence of low ratios so long ago," writes the Sanitary Commissioner, "is a warning not to be too ready to attribute low ratios nowadays to recent sanitary "improvements." Mention is not made in the Report of the prophylactic effects of the anti-cholera inoculation which some of the tea-garden coolies underwent before embarking on the steamers which conveyed them to Assam. In the Sanitary Report for the province of Bengal, it is claimed that "the number of cases of cholera among uninoculated and inoculated coolie "emigrants on board the steamers proceeding from Goalundo to Dibrugarh from January to "September clearly show the advantage of being inoculated against cholera." It would not, probably, be difficult to trace the subsequent history of inoculated coolies employed on the tea estates, or to ascertain if they had enjoyed any special immunity from cholera as compared with those who had not been inoculated.

5. The mortality from *small-pox* was unusually low. The severe epidemic of the preceding year, doubtless, greatly reduced the number of susceptible subjects, and thus contributed to the abeyance in which the disease remained during the year under report. Whilst in 1902, a death-rate of 1·26 was ascribed to small-pox, the rate for the year under report was only 0·21. The marked reduction in the number of vaccinations performed during 1903-04 might likewise, to some extent, be credited to the epidemic of the previous war. During the prevalence of small-pox the people are more willing, or at least have less objection, to allow their children to be vaccinated. Moreover, an epidemic reduces the number of persons in need of vaccination, one attack of small-pox generally rendering the survivor immune from a subsequent one.

6. During the year under report, *plague* paid its first visit to Assam. Between the appearance of the first case on the 16th of May and the last on the 3rd of July, 37 attacks, with 28 deaths, were reported. It is suggestive of the mode of introduction of the disease, that the first case appeared in the foreign grain bazaar of Dibrugarh. Most of the cases which followed also occurred in the same bazaar. "It had been noticed for a few days that rats were dying "in great numbers" in the same neighbourhood. In the combat against plague, the experience gathered in other parts of India was turned to good account in Assam: "every endeavour was "made to gain the sympathy and co-operation of the people, the result being that there was "no popular opposition" to the measures adopted for dealing with the outbreak. These measures were speedily and completely successful.

7. The mortality from *fever* was somewhat less than in the preceding year, the death-rate falling from 14·72 per thousand of population in 1902 to 14·22 in the year under report. The form of fever known as kálá-ázár had 5,033 deaths attributed to it; the lowest number recorded

under this heading during any one of the past 10 years. There would, however, appear to be still some uncertainty in the diagnosis of kálá-ázár which may affect the number of deaths ascribed to it.

8. The inquiry into the causes of the higher mortality from *dysentery* and *diarrhœa* amongst tea-garden coolies than among the general population has, so far, led to no definite conclusion. The suggestion made in our *Memorandum* for last year, that the difference might be due rather to difference of diagnosis than to greater fatality from bowel complaints amongst tea-garden coolies, would appear to have some foundation. "Both Civil Surgeons and European garden "doctors are of opinion," writes the Sanitary Commissioner, "that the return of dysentery "from tea-gardens is, in its way, quite as inaccurate as that from villages." Apparently, the *gaonbura* tends to return too many deaths under "fever," the garden baboo too many under "dysentery." But accurate information on the subject he reports to be practically unattainable.

9. No one large sanitary work was undertaken in the province in 1903, and no provincial scheme of any importance was under consideration. The question of how to give still further encouragement to the sale of quinine among the people is engaging attention; the amount sold during the year increased and decreased, except in the case of a single district, with the increase and decrease of fever mortality.

In Assam: "The local conditions are not favourable to the establishment and success of "mosquito brigades. At military stations, especially Kohima, real efforts were made, but "reduction of fever is not yet strikingly apparent."

3rd June, 1905.

No. 9.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Madras for 1903.

Preceding the Sanitary Commissioner's Report a page is given to a brief sketch of the proceedings of the Sanitary Board. Although its Report comes first in the volume, the Board's labours consist principally in examining works of sanitary improvement after these have undergone scrutiny by the Sanitary Commissioner and Sanitary Engineer. Some idea of the extent of these labours may be gathered from the number and importance of the works dealt with during the year. It is stated that there were 149 such works, estimated to cost, in the aggregate, upwards of seventeen lakhs of rupees. An alteration introduced by Government, in accordance with which works estimated to cost less than one thousand rupees shall not in future come before the Sanitary Board for consideration, will have the effect of relieving the Board of a mass of comparatively petty details hitherto thrown upon it when no work of an estimated cost exceeding two hundred rupees could be undertaken without its previous sanction. The effect of this alteration will be to expedite the execution of the smaller schemes of sanitary improvement, whilst placing more time at the disposal of the Board for the consideration of works of greater importance.

2. In the presidency as a whole the year was one of abundant rainfall, the average of the preceding ten years having been exceeded by no less than 29·6 inches. In one district only, that of Tinivelly, was the rainfall largely in defect. The favourable monsoons were followed by favourable harvests and a fall in the price of food-grains. These conditions favourably affected the public health. The birth-rate rose to 31·2 from 28·2 in the previous year, whilst the death-rate rose only to 22·2 from a mean ratio, for the previous five years, of 21·2. The increase of the death-rate was small when regarded in connection with the increase of the birth-rate. The natural increase of the population, or the number by which the births exceeded the deaths during the year, was 768,735. The increase in both the birth and the death-rate is attributed, in part, to improvement in the registration of vital statistics. This improvement, however, "the Govern-"ment regret to remark advances but slowely." That the registration of births and deaths for the presidency, as a whole, and especially as regards the rural areas, is still very defective is evident from a comparison of the birth and death-rates in municipalities with those recorded in rural circles. Whilst the births registered in municipalities yielded a birth-rate per thousand of population of 35·7, those recorded in rural circles yielded a rate of 31·2; and whilst municipalities returned a death-rate of 32·7, the rate for rural circles was only 21·5, according to Form II of the Appendix. Quoting, again, from the Government review of the Report: "In respect of the registration of deaths in municipalities the latter results obtained there as "compared with those in the districts were due partly to the registration of vital statistics being "compulsory and partly to increased attention to the subject."

3. Of the chief diseases, *cholera* showed some decrease in fatality, the death-rate due to it falling from ·8 per thousand of population in the preceding year to ·7 in the year under report. It is significant that the three towns most severely affected "have notoriously evil water supplies." The Sanitary Commissioner describes an outbreak, the origin of which is traced to the contamination of the river Adyar by the cholera discharges from a bricklayer attacked by the disease on its bank. The inhabitants of Guindy, who draw their water supplies from the Adyar, at a point about a quarter of a mile farther down the same side of the river, were attacked by cholera three days after the man was known to be suffering. The inference is, that the cholera

discharges were washed into the river by the rain which fell on the night after the bricklayer was attacked, carried down to Guindy, and there infected the inhabitants. Nothing is said of the source from which the bricklayer was infected; but, if he was a resident of the place, the circumstance of his having been infected indicates that the disease was locally existent, and this conceded, it might be a question whether he and the inhabitants of Guindy did not contract the disease from a common source. If the endeavour to trace to its exact cause an outbreak of cholera in jails or lunatic asylums, institutions immediately under the daily observation of medical officers trained in scientific methods of investigation, almost invariably ends in failure, it is but natural that the discovery of the orign of an outbreak, such as that described, amongst the general population should require for its confirmation evidence of the most convincing nature. The theory which the Sanitary Commissioner holds regarding the cholera microbe would doubtless explain much that is obscure in the history of cholera. He says: "The chances "are, irrespective of well-recognized facts following introduction to a locality, that, in certain "areas, the cholera microbe exists in water in a modified or feeble condition, and that the "epidemic appearance is due to the enhancement of its virulence following inflow of suitable "pabulum, especially from the subsoil and possibly from the surface." He adds: "the "bacteriologist has left the sanitarian with no more information than was obtained by Koch "originally as to the behaviour of the cholera microbe." In the case of the outbreak at Guindy, it is not stated if the cholera microbe was looked for and detected in the contaminated river water, which is assumed to have conveyed infection from the bricklayer to the people of Guindy.

4. The mortality from *small-pox*, as from cholera, showed a decrease as compared with that recorded in the preceding year. For the presidency as a whole the death-rate credited to this disease was only ·4 against ·7 in 1902. The comparative immunity from small-pox enjoyed by the municipal population, numbering nearly two and a half millions, can only be ascribed to the protective influence of vaccination. In all of the municipalities vaccination is compulsory, with the result that the ratio of the municipal population successfully vaccinated was equal to 49·9 per thousand, as compared with only 29·7 for the presidency as a whole; and that the death-rate from small-pox was only 0·1 per thousand in municipalities as compared with 0·4 in rural areas. The progress made by vaccination during the year under report is not considered to have been satisfactory. The numbers vaccinated show a considerable decrease as compared with the numbers vaccinated during the previous year. The chief causes assigned for the decrease in the districts in which this was greatest are insufficient, or irregular, supply of vaccine lymph, absence of vaccinators without substitutes, and non-prevalence of small-pox. So long as there is but a single Inspector of Vaccination, burdened with multifarious important duties in addition to superintending vaccination, efficient administration of the department cannot reasonably be expected. The officer in question, "being practically an educational officer, was not available, "except for sufficient time daily to see to *routine* papers of the Vaccination Department." The history of vaccination throughout India clearly shows that efficient supervision is absolutely essential to its successful promotion. Hitherto, this cannot be said to have been provided in Madras whilst the officer in charge of the Department has been so occupied with other duties as to be unable to find time to attend to more than the routine papers of the Department. Calf-to-arm vaccination yielded the highest percentage of successful cases, 98·5; this was closely followed by animal lymph in tubes and plates. In the 441,646 cases in which glycerinated lymph was used by local fund vaccinators, the percentage of success attained was only 86·9. Obviously, there is much room for improvement as regards the quality, as well as the sufficiency and regular distribution of the lymph supply.

5. To *plague* were ascribed 13,291 deaths, or 2,496 more than in the previous year. It is stated that, of these deaths, 7,088 occurred amongst males and only 6,203 amongst females. In his Report for 1902, the Sanitary Commissioner of the United Provinces of Agra and Oudh states that females died in considerably greater numbers than males, and this difference of liability to death from plague between the sexes, he thinks, "may very possibly be due to the facts that Native "females spend more time inside their houses and court-yards than do men, and moreover do not "so habitually wear shoes." In the Madras Presidency, to whatever cause due, the liability to die of plague is, on the contrary, shown by the returns to be less amongst females than amongst males. As the result of his observations, Colonel King has come to the important conclusion that it is unnecessary to adopt the theory of "recrudescence" to explain fresh outbreaks of plague in towns which had suffered from previous epidemics of the disease. "Investigation of records by "me for this purpose," he writes, "goes to prove that town after town that has been infected "has suffered solely from importation and not from recrudescence of the disease of a past season: "and that, similarly, it by no means follows that a town once infected may be visited again by "the disease."

6. *Fever*, as usual in the Madras Presidency, has ascribed to it a far lower death-rate than in the other provinces, excepting Burma. Comparing the fever death-rates in the three contiguous provinces; whilst Madras records a ratio of 8·4 deaths from fever per thousand of population, that recorded for Bombay is 14·05, and for Bengal, 22·23. How much of the difference between these figures is due to difference in the incidence of the disease, and how much to greater or less inaccuracy in the registration of deaths according to their causes in each of these provinces is uncertain; but the proportion of deaths recorded under the heading of "all "other causes" in each of the three provinces suggests that many deaths ascribed to fever in Bombay and Bengal are more correctly recorded under the head of "all other causes" in Madras. The death-rate ascribed to "all other causes" in Madras for the year under report was 10·2, in Bombay 7·82, and in Bengal 5·78. With the object of ascertaining the effect of the "conjoint "use of mosquito larvæ destruction, administration of quinine to human beings and minor "engineering works" in diminishing or extinguishing malaria, the Government of Madras has

directed that funds be allotted by local bodies for experiments in six carefully selected areas. "There are here, therefore," the Sanitary Commissioner remarks, "the elements for a thoroughly "honest trial of modern methods of dealing with malaria."

7. No new sanitary scheme of importance has been undertaken by any of the municipalities during the year, nor, in the opinion of the Sanitary Commissioner, is any such likely to be undertaken until the Government is in a position to again offer grants-in-aid. Nor in rural areas does sanitary progress appear to be more marked. The education of certificated Sanitary Inspectors has been made more thorough by the addition of a course of sanitary engineering to their training. The employment of those inspectors in towns and districts cannot fail to diffuse a knowledge of the elementary principles on which the public health depends, and by degrees to teach the people to take a practical interest in local sanitary matters.

3rd June, 1905.

No. 10.

Memorandum by the Army Sanitary Commission on the Report of the Sanitary Commissioner of Bombay for 1903.

1. The vital statistics of the year give no indication of improvement in the health of this presidency. On the contrary, with the exception of 1900, when severe famine combined with epidemic cholera, fever, and plague to swell the mortality returns, the death-rate was higher than any recorded during the preceding ten years. The climatic conditions of the year, as far at least as can be gathered from the account given of its rainfall, do not appear to have differed widely from normal. The monsoon broke in June, but was weak in nearly all parts of the country in that month. In July, however, it gathered strength and yielded a rainfall in excess of the average. In August the fall was generally in defect in two of the divisions, and in the other two in excess in some parts and in defect in others. In the months of September and October, it is described as having been generally sufficient. Except in Gujarát, where no rain fell, there were in the other divisions more or less frequent and light, or heavy, showers in November, whilst December yielded a few cents at some stations and was rainless at the rest.

2. Excepting in the famine year 1900 and in the year succeeding it, the fecundity of which latter would naturally be affected by the conditions which prevailed during its predecessor, the number of children born was lower than that recorded in any of the preceding ten years. The unprecedented sickness and mortality caused by plague doubtless contributed to diminish the birth-rate of the year; but, as pointed out in the Government review of the Report, "in view "of the opinion that the decrease of the birth-rate in Gujarát is to be ascribed to the incidence "of plague, it is remarkable that the birth-rate has been least affected in those districts where "the incidence of plague has been heaviest." It will be seen, on referring to Annual Forms I and II in the Appendix, that the three districts which recorded the highest birth-rates for the year all suffered severely from plague, Ahmadnagar with the highest birth-rate of all, 43·30, recording from plague alone a death-rate of 25·63 per thousand of its population. On the other hand, of the three districts which recorded the highest death-rates from plague none recorded a birth-rate below the general provincial rate of 31·22. As usual, the six Sind districts yield abnormally low birth-rates, none of these latter reaching 30, and two of them falling below 20 per thousand of population. In the two districts mentioned, the proportion of male to female births is 134·66 to 100 in the one, and 138·14 in 100 in the other. The explanation alike of the low birth-rates and of the abnormally high proportion of male to female children is doubtless to be found in defective registration.

3. The 811,525 deaths recorded during the year yield a death-rate of 43·91 per thousand of population, and exceed the number of births by 234,576. The increase in the mortality caused by plague was chiefly accountable for this high death-rate. Plague was accountable for more than a third of the total mortality of the year, and reasons are given for the belief that even this does not represent the full measure of the loss of life caused by it. The provincial mortality amongst infants of less than a year of age was, in the case of males, 219·57, and of females 206·70 of every 1,000 born; but in certain registration circles these rates were much exceeded. The principal causes to which this high infantile mortality was due are without doubt correctly ascribed by the Sanitary Commissioner to "improper and insufficient food, bad management, use "of opiates, neglect, early marriages, and debility of mothers." These causes are not confined to the Bombay Presidency, although the mortality due to some of them may have been increased during the years of unusual sickness and distress through which the province has recently been passing. In the year under report "the widespread influence of plague struck heavily at both "mothers and infants."

4. Only once during the preceding twenty years has *cholera* been in so complete abeyance. The number of deaths ascribed to it was only 1,825, giving a ratio of ·09 per thousand of population. The record of the mortality caused by the disease in preceding years shows the wide annual variations in its prevalence which are so striking features in the history of cholera. Satisfactory explanations of the causes of these variations have yet to be found. In concluding his remarks on cholera, the Sanitary Commissioner writes: "An inquiry into the influence of

" local water supplies on the propagation of the disease would have been interesting and valuable, " but until the strength of the Department in Sind is increased, scientific inquiries into the local " causes of cholera epidemics are impracticable."

5. The deaths from *small-pox* numbered only 2,732, and of these more than half occurred in the City of Bombay. The resulting death-rate from this disease, during the year under report, was 0·15 as compared with 0·23, the mean of the previous five years. In spite of the difficulties it had to contend against during a year of exceptionally severe plague prevalence, the progress made by vaccination was not unsatisfactory. The number of primary vaccine operations shows an increase over the number for the preceding year of 2·67 per cent., whilst the percentage of successful cases was as high as 98·3. On the other hand, there was a decrease of 5,309 in the number of re-vaccinations. The high percentage of success recorded in re-vaccination cases has attracted the attention of the Sanitary Commissioner, who is doubtless correct in thinking that this is probably due to preceding imperfect primary vaccination. In this presidency, humanized vaccine lymph is still used in the vast majority of cases, and the percentage of success following its use is everywhere very high, being in none of the registration circles less than 98·51 and in most of them exceeding 99 in primary vaccination. In Bombay City humanized has been entirely superseded by animal lymph. The latter is credited with a percentage of 99·01 successful cases. So far, the endeavour to preserve vaccine lymph by mixing it with glycerine or lanoline has not, to judge from results, been attended with much success. In primary vaccination the percentage of successful cases following the use of glycerinated lymph is stated to have been only 87·15, whilst lanoline paste yielded a percentage of 93·15 in one of the registration circles in which it was used, and only 84·4 in the other.

6. The mortality from *fever* has continued to diminish since 1900, when the deaths ascribed to it exceeded half a million, until, during the year under report, they were only somewhat over a quarter of a million. But whilst the classification of deaths according to their exact causes is still so defective, little reliance can be placed on these numbers. Amongst the deaths attributed in the returns to fever and respiratory diseases, there is reason to believe that not a few, really due to plague, have been included. The subject of the prevention of malarial fevers by the destruction of infection-bearing mosquitos is briefly dealt with in the report. Two medical officers appear to have organised " mosquito brigades," and both claim that the employment of these was attended with encouraging results; but no facts are given in support of this claim. Malaria, according to the report of the Deputy Sanitary Commissioner, Southern Registration District, is especially rife in the forest areas of Kánara and Dhárwár; but the reduction of mosquitos in these areas is considered to be impracticable. The distribution of quinine and the organisation of travelling dispensaries in the most malarious parts of Kánara, are the measures chiefly relied on for mitigating the severity of the fevers from which the inhabitants of those jungles suffer.

7. The mortality from *plague*, instead of decreasing, was the greatest yet recorded since the disease first appeared in Bombay towards the end of 1896. The deaths attributed to it numbered 281,269, or nearly a hundred thousand more than in the previous year. Only two of the 25 collectorates of the presidency were entirely free from the disease during the year. The same sudden fall in the number of deaths from plague, which was recorded in May and June of the previous year, was also a marked feature of its history during the same months of the year under report. As usual, the inhabitants of town circles suffered more severely than those of country circles. Whilst the death-rate from plague in districts was 13·91 per thousand of population, in towns it was 23·89; the rate for the province, as a whole, having been 15·22. A return is given of the deaths which occurred from plague amongst persons inoculated with the " anti-plague prophylactic." Those deaths number 2,156. Commenting on these figures, the Sanitary Commissioner writes: " To judge of the value of the plague prophylactic a return of " *all persons inoculated, and of those how many were subsequently attacked and died* of the " disease, is necessary. The return received from the Plague Department merely reports the " deaths amongst inoculated persons."

8. According to the returns, the mortality from *dysentery and diarrhœa*, as in the case of that from fever, has been on the decrease since 1900. The deaths ascribed to these diseases, during the year under report, numbered only 55,443, or about a fourth of the number recorded in 1900. As in the case of fevers, however, much reliance cannot be placed on these figures. The statistics annually furnished by medical practitioners in the United Provinces, and which may be assumed to be approximately accurate, support the belief that, whilst the number of deaths recorded under the head of " fever," in the returns prepared from the reports made by the village watchmen, is much exaggerated, the number recorded under the heading " dysentery " and diarrhœa " is, on the other hand, greatly understated. The table on page 18 of the Report shows that the deaths registered under the heading " other causes," which began to increase from the year 1896, when plague first appeared in the presidency and continued to increase year by year until they attained a total of 342,027 in 1900, have, since the latter year, again been decreasing until, in the year under report, they number only 144,510. The decrease is more apparent than real, however, and is mainly due to the separate registration of deaths from respiratory diseases, which, previous to the last two years, were included under the head of " other causes." During the year under report 59,349 deaths were returned as due to respiratory diseases; and if these are added to the deaths due to " other causes," the total of the latter will be raised to 203,859.

9. The continuance, with increasing virulence, of the plague epidemic, whilst demonstrating the urgent need for sanitary improvements, has depleted the funds available for their execution. Quoting from the annual report of the Sanitary Board, which met once during 1903: " With

directed that funds be allotted by local bodies for experiments in six carefully selected areas. "There are here, therefore," the Sanitary Commissioner remarks, "the elements for a thoroughly "honest trial of modern methods of dealing with malaria."

7. No new sanitary scheme of importance has been undertaken by any of the municipalities during the year, nor, in the opinion of the Sanitary Commissioner, is any such likely to be undertaken until the Government is in a position to again offer grants-in-aid. Nor in rural areas does sanitary progress appear to be more marked. The education of certificated Sanitary Inspectors has been made more thorough by the addition of a course of sanitary engineering to their training. The employment of those inspectors in towns and districts cannot fail to diffuse a knowledge of the elementary principles on which the public health depends, and by degrees to teach the people to take a practical interest in local sanitary matters.

In the months of September and October, it is described as having been generally sufficient. Except in Gujarát, where no rain fell, there were in the other divisions more or less frequent and light, or heavy, showers in November, whilst December yielded a few cents at some stations and was rainless at the rest.

2. Excepting in the famine year 1900 and in the year succeeding it, the fecundity of which latter would naturally be affected by the conditions which prevailed during its predecessor, the number of children born was lower than that recorded in any of the preceding ten years. The unprecedented sickness and mortality caused by plague doubtless contributed to diminish the birth-rate of the year; but, as pointed out in the Government review of the Report, "in view "of the opinion that the decrease of the birth-rate in Gujarát is to be ascribed to the incidence "of plague, it is remarkable that the birth-rate has been least affected in those districts where "the incidence of plague has been heaviest." It will be seen, on referring to Annual Forms I and II in the Appendix, that the three districts which recorded the highest birth-rates for the year all suffered severely from plague, Ahmadnagar with the highest birth-rate of all, 43·30, recording from plague alone a death-rate of 25·63 per thousand of its population. On the other hand, of the three districts which recorded the highest death-rates from plague none recorded a birth-rate below the general provincial rate of 31·22. As usual, the six Sind districts yield abnormally low birth-rates, none of these latter reaching 30, and two of them falling below 20 per thousand of population. In the two districts mentioned, the proportion of male to female births is 134·66 to 100 in the one, and 138·14 in 100 in the other. The explanation alike of the low birth-rates and of the abnormally high proportion of male to female children is doubtless to be found in defective registration.

3. The 811,525 deaths recorded during the year yield a death-rate of 43·91 per thousand of population, and exceed the number of births by 234,576. The increase in the mortality caused by plague was chiefly accountable for this high death-rate. Plague was accountable for more than a third of the total mortality of the year, and reasons are given for the belief that even this does not represent the full measure of the loss of life caused by it. The provincial mortality amongst infants of less than a year of age was, in the case of males, 219·57, and of females 206·70 of every 1,000 born; but in certain registration circles these rates were much exceeded. The principal causes to which this high infantile mortality was due are without doubt correctly ascribed by the Sanitary Commissioner to "improper and insufficient food, bad management, use "of opiates, neglect, early marriages, and debility of mothers." These causes are not confined to the Bombay Presidency, although the mortality due to some of them may have been increased during the years of unusual sickness and distress through which the province has recently been passing. In the year under report "the widespread influence of plague struck heavily at both "mothers and infants."

4. Only once during the preceding twenty years has *cholera* been in so complete abeyance. The number of deaths ascribed to it was only 1,825, giving a ratio of ·09 per thousand of population. The record of the mortality caused by the disease in preceding years shows the wide annual variations in its prevalence which are so striking features in the history of cholera. Satisfactory explanations of the causes of these variations have yet to be found. In concluding his remarks on cholera, the Sanitary Commissioner writes: "An inquiry into the influence of

local water supplies on the propagation of the disease would have been interesting and valuable, "but until the strength of the Department in Sind is increased, scientific inquiries into the local "causes of cholera epidemics are impracticable."

5. The deaths from *small-pox* numbered only 2,732, and of these more than half occurred in the City of Bombay. The resulting death-rate from this disease, during the year under report, was 0·15 as compared with 0·23, the mean of the previous five years. In spite of the difficulties it had to contend against during a year of exceptionally severe plague prevalence, the progress made by vaccination was not unsatisfactory. The number of primary vaccine operations shows an increase over the number for the preceding year of 2·67 per cent., whilst the percentage of successful cases was as high as 98·3. On the other hand, there was a decrease of 5,309 in the number of re-vaccinations. The high percentage of success recorded in re-vaccination cases has attracted the attention of the Sanitary Commissioner, who is doubtless correct in thinking that this is probably due to preceding imperfect primary vaccination. In this presidency, humanized vaccine lymph is still used in the vast majority of cases, and the percentage of success following its use is everywhere very high, being in none of the registration circles less than 98·51 and in most of them exceeding 99 in primary vaccination. In Bombay City humanized has been entirely superseded by animal lymph. The latter is credited with a percentage of 99·01 successful cases. So far, the endeavour to preserve vaccine lymph by mixing it with glycerine or lanoline has not, to judge from results, been attended with much success. In primary vaccination the percentage of successful cases following the use of glycerinated lymph is stated to have been only 87·15, whilst lanoline paste yielded a percentage of 93·15 in one of the registration circles in which it was used, and only 84·4 in the other.

6. The mortality from *fever* has continued to diminish since 1900, when the deaths ascribed to it exceeded half a million, until, during the year under report, they were only somewhat over a quarter of a million. But whilst the classification of deaths according to their exact causes is still so defective, little reliance can be placed on these numbers. Amongst the deaths attributed in the returns to fever and respiratory diseases, there is reason to believe that not a few, really due to plague, have been included. The subject of the prevention of malarial fevers by the destruction of infection-bearing mosquitos is briefly dealt with in the report. Two medical officers appear to have organised "mosquito brigades," and both claim that the employment of these was attended with encouraging results; but no facts are given in support of this claim. Malaria, according to the report of the Deputy Sanitary Commissioner, Southern Registration District, is especially rife in the forest areas of Kánara and Dhárwár; but the reduction of mosquitos in these areas is considered to be impracticable. The distribution of quinine and the organisation of travelling dispensaries in the most malarious parts of Kánara, are the measures chiefly relied on for mitigating the severity of the fevers from which the inhabitants of those jungles suffer.

7. The mortality from *plague*, instead of decreasing, was the greatest yet recorded since the disease first appeared in Bombay towards the end of 1896. The deaths attributed to it numbered 281,269, or nearly a hundred thousand more than in the previous year. Only two of the 25 collectorates of the presidency were entirely free from the disease during the year. The same sudden fall in the number of deaths from plague, which was recorded in May and June of the previous year, was also a marked feature of its history during the same months of the year under report. As usual, the inhabitants of town circles suffered more severely than those of country circles. Whilst the death-rate from plague in districts was 13·91 per thousand of population, in towns it was 23·89; the rate for the province, as a whole, having been 15·22. A return is given of the deaths which occurred from plague amongst persons inoculated with the "anti-plague prophylactic." Those deaths number 2,156. Commenting on these figures, the Sanitary Commissioner writes: "To judge of the value of the plague prophylactic a return of "*all persons inoculated, and of those how many were subsequently attacked and died* of the "disease, is necessary. The return received from the Plague Department merely reports the "deaths amongst inoculated persons."

8. According to the returns, the mortality from *dysentery and diarrhœa*, as in the case of that from fever, has been on the decrease since 1900. The deaths ascribed to these diseases, during the year under report, numbered only 55,443, or about a fourth of the number recorded in 1900. As in the case of fevers, however, much reliance cannot be placed on these figures. The statistics annually furnished by medical practitioners in the United Provinces, and which may be assumed to be approximately accurate, support the belief that, whilst the number of deaths recorded under the head of "fever," in the returns prepared from the reports made by the village watchmen, is much exaggerated, the number recorded under the heading "dysentery "and diarrhœa" is, on the other hand, greatly understated. The table on page 18 of the Report shows that the deaths registered under the heading "other causes," which began to increase from the year 1896, when plague first appeared in the presidency and continued to increase year by year until they attained a total of 342,027 in 1900, have, since the latter year, again been decreasing until, in the year under report, they number only 144,510. The decrease is more apparent than real, however, and is mainly due to the separate registration of deaths from respiratory diseases, which, previous to the last two years, were included under the head of "other causes." During the year under report 59,349 deaths were returned as due to respiratory diseases; and if these are added to the deaths due to "other causes," the total of the latter will be raised to 203,859.

9. The continuance, with increasing virulence, of the plague epidemic, whilst demonstrating the urgent need for sanitary improvements, has depleted the funds available for their execution. Quoting from the annual report of the Sanitary Board, which met once during 1903: "With

" the exception of Ahmedabad and Kárachi none of the Municipalities were in a position t
" undertake costly works, their available funds being required for minor works which had been
" postponed owing to the expenditure and loss of revenue due to plague and famine."

10. The report of the Health Officer of the Port of Bombay, attached as an appendix to the Sanitary Report, is a record of strenuous and successful effort to prevent the dissemination of infectious diseases. No fewer than 14,432 vessels of all sorts, with crews and passengers numbering 719,322, were examined during the year. The following quotation will give some idea of the variety and nature of the diseases discovered at these inspections:—" At the outward " and inward inspections, and on board vessels lying in the harbour and docks, 19 cases of " measles, 77 cases of plague, 2 cases of cholera, 238 cases of small-pox, and 1 case of scarlatina " were detected." Up to the present, no case of sleeping-sickness has been met with during these inspections.

3rd June, 1905.

No. 11.

Memorandum by the Army Sanitary Commission on the Administration Report of the Town of Calcutta for 1903–04.

The history of the Health Department for the year is disposed of in little more than four pages. This brevity is, no doubt, in part, due to the exclusion of plague from the list of diseases with which the Health Officer had to deal. " Plague was administered by a special department " independent of the Health Department." The omission from a Health Report of some account of the disease which caused more loss of life than any other seems somewhat of an anomaly. But for the prevalence of plague, the year under review would have been a comparatively healthy one. Excluding the mortality from this disease, the death-rate would not have exceeded 25·4 per thousand of population. The rainfall measured only 54·14 inches, as compared with 62·28 in the preceding year; and the mortality from fever and bowel complaints was the lowest recorded in any one of the preceding ten years. In the case of almost every article of the ordinary food of the people, there was a marked increase in the price over that which ruled in 1902-03; but the Health Officer makes no mention of any influence which either the climatic conditions or prices of foodstuffs may have exercised on the public health.

2. Calculated on the number of births registered during the year, the birth-rate was only 15·5 per thousand of population. Even when allowance is made for the disparity in the proportion of the sexes in the population of Calcutta, which consists approximately of two-thirds of males to one-third of females, the Health Officer estimates that if all the births had been recorded the birth-rate should not be less than 26 per thousand of population. With the object of improving birth registration, a new system was experimentally adopted in one district of the town for nine months, with the result that the number of births recorded during those months showed an increase of 51 per cent. The Health Officer considers the new method of registration to have been so successful in the district in which it was tried, that its extension to the other districts would be advisable.

3. The death-rate recorded was 35·1 per thousand of the population. This high death-rate is ascribed to a recrudescence of plague, excluding the mortality from which it would have been only 25·4. The mortality amongst children under one year of age was, as usual, high, reaching, as it did, a ratio of 314·3 per thousand of children of that age living. An examination of Tables IV and V of Appendix C shows remarkable differences between the birth and death-rates recorded in the several districts of the municipality. Whilst in five of these birth-rates rising from 20 to upwards of 26 per thousand of population are recorded, in other seven the rates are less than 10 per thousand. So, as regards mortality, several districts returned death-rates of less than 20 per thousand of population, and others rates exceeding 40.

4. Of the history of the plague epidemic no account is given in the report, beyond the mere record of the number of deaths ascribed to it in the returns of mortality. From these returns it appears that 8,222 persons died from this disease; a number greater than than recorded for any one year, excepting 1900, since the commencement of the present epidemic in Calcutta in 1898.

5. Sanitary improvement, as measured by diminution of mortality from *cholera*, would appear to be inappreciable. Taking the ten years preceding 1903, five of those record a number of deaths from cholera greater, and five of them a number less, than that returned for the year under report, whilst the mean number of deaths for those ten years is less than the number for the year under report. Such a record can scarcely be regarded with satisfaction, and may be contrasted with the marked reduction in the mortality from cholera which the returns show it to be possible to effect by persistent and successful endeavour to promote sanitary improvement, as exemplified in the case of the armies and jails of India. Commenting on the continued high rate of mortality from cholera in Calcutta, the Health Officer writes:—" There is very " little that can be done to check it, as it is in a large measure due to importation by pilgrims " from outside, and in the town, as Dr. Mullan, the District Health Officer, has recently collected " a number of cases to show, from the use of the water of Tolly's nullah in connection with the

"pujahs of Kalighat Temple." As noted in a previous *memorandum*, the assertion, now repeated, that the disease is brought into Calcutta from outside is unsupported by proof. Calcutta is still a notoriously insanitary town; and if the question of whether cholera is imported into Calcutta from the surrounding country or whether, on the contrary, it is spread from Calcutta into the surrounding country, is to be decided on the relative sanitary condition of the two as measured by the general death-rate, or, by what is usually regarded as a better test, the infantile death-rate, recorded in each, the probability would be in favour of the assumption that, instead of Calcutta being infected by cholera from outside, the country was infected by cholera from Calcutta. In the 24 Parganas the general death-rate amongst the population during the year under report was 31·7 per thousand, and in Calcutta 35·10. The death-rate in the former, among children under one year of age, per thousand births was 184·6, and in Calcutta 315·6. Moreover, the general death-rate in Calcutta should have been lower, instead of higher, than that recorded in the 24 Parganas, on the supposition that both were equally insanitary, seeing that the proportion of infants in the Calcutta population was far less than the proportion of infants in the 24 Parganas. The recorded birth-rate for the 24 Parganas was 32·18 and in Calcutta 15·54, or less than half; in other words, the proportion of the population of an age when death is most likely to occur was far greater in the 24 Parganas than in Calcutta. That cholera was less fatal in Calcutta than in the surrounding country was probably due to the advantage which the inhabitants of the former have over the latter, in that they enjoy a purer water supply; but the high mortality caused by the disease, notwithstanding this purer water supply, may be taken as evidence that cholera still finds in Calcutta insanitary conditions favourable to its maintaining a hold which, as yet, shows but little sign of weakening.

6. *Small-pox* was in abeyance during the year, only 50 deaths having been ascribed to it, as compared with 127 in the preceding year and with 2,997 in 1901. The progress being made by vaccination affords little guarantee that Calcutta will long escape a recurrence of one of those severe epidemics of small-pox from which it has suffered in three out of the preceding ten years. During the year under review, "the "vaccination returns again show a falling-off, on the whole, though there was a slight increase "in Districts I and III." When the Health Officer wrote his Report, Calcutta was still without the means of providing its own supplies of vaccine lymph and had to have recourse to the Madras Municipality for the purchase of "glycerised vaccine." When in communication with the Madras Municipality regarding the supply of vaccine lymph, the opportunity might be taken of becoming acquainted with the system of vaccination which has succeeded in almost extinguishing small-pox in that city. Possibly, if carried out with the same thoroughness in Calcutta, that system might be found to be no less successful than the returns of small-pox mortality prove it to have been in Madras.

7. Fewer deaths were registered under the head of *fever* than in any one of the preceding ten years. The number of deaths attributed to this cause was 4,869, as compared with 8,036, the mean for the preceding ten-year period. This decrease, the Health Officer attributes, to some extent, to the registration of more deaths under the head of "other causes"; although, apart from this, he believes there has been an appreciable diminution in malarial fever in Calcutta within the last few years. Only 51 deaths were reported to have been caused by *enteric fever*. The number of deaths due to this form of fever the Health Officer believes to be understated, "as enteric in the native is apt to pass unrecognised, and to be confused with "other febrile complaints, and it is quite exceptional for medical practitioners in the town to "notify their cases." The belief expressed by the Health Officer that there are more deaths from enteric fever than the returns would indicate seems to be founded on no exact evidence. The statistics of mortality in the Native Army and in the jails of India do not support the often-repeated opinion that enteric fever is a common cause of death amongst natives.

8. The mortality from *dysentery and diarrhœa* was less than in any one of the preceding ten years. The number of deaths attributed to these diseases was 2,677, as compared with 3,254, the mean of the preceding ten-year period. This reduction in the mortality from bowel complaints suggests improved quality of the food and water used by the people.

9. The execution of the suburban drainage scheme continues to make progress, although, as might have been expected, not without some departures from the original scheme, as well as interruptions due to the temporary stoppage of funds. It appears that the work on one sewer, "which had thus been interrupted in 1900, was not resumed till October 1903." As a result of these interruptions, parts of the completed portions of the scheme could not be brought into use until the completion of other portions on which work had been stopped.

10. The introduction of the continuous system of water supply is said to make satisfactory progress, although, for reasons stated in the Government Resolution on the Report, its extension throughout Calcutta will not be accomplished within the time originally contemplated in the Act. Chemically considered, the filtered water supply of Calcutta is stated to have maintained its character as a wholesome water. The only unsatisfactory feature connected with the tests applied to ascertain the state of purity of the water was "the continued presence of bacteria "of the Colon group, which were found in every examination of the filtered water in relatively "large numbers."

5th June, 1905.

No. 12.

Memorandum by the Army Sanitary Commission on the Administration Report of the Madras Municipality for 1903-04.

The year 1903 was comparatively healthy. The total rainfall amounted to 79·62 inches, and was in excess of the average by no less than 30·60 inches. The percentage of humidity was above normal throughout the year. Accompanying the unusual amount of rainfall and humidity the mean temperature was below the average in all the months of the year excepting the first three and October; whilst in April it was normal. "The highest temperature recorded during "the year was 103°·1 on 27th June, and the lowest 65°·3 on 8th December."

2. The *birth-rate* increased from 34·8 in the preceding year to 38·9 in the year under review, but was still below the average for the preceding decade which was 40·1. The proportion of still to live births was 3·6 of the former to every 100 of the latter. In the City of Bombay 11·1 still births to every 100 live births are recorded. No entirely satisfactory explanation has yet been given of the wide difference between the ratios of still to live births in the two cities. In another particular, also, their vital statistics show a wide divergence: whilst the ratio of births of male children to births of female children was 104·4 of the former to every 100 of the latter in Madras, it was 108·09 to every 100 in Bombay.

3. The *death-rate*, although still far higher than it should be, decreased from 42·0 per thousand of population in the previous year to 37·7 in the year under review. In two of the wards of the city the death-rate exceeded 47 per thousand of population. In both of these wards the marked insanitary conditions prevailing would sufficiently account for the excessive mortality. The divisions of the city to which these two wards belong return the highest death-rates from fevers. The infantile mortality continues high. Calculated on the number of children under one year of age living when the last census was taken, the death-rate was 411·6 per thousand; but calculated on the number of births recorded during the year it was 283·3, or considerably less than in the previous year when it was 303·9. Commenting on the high rate of mortality among children under one year of age, the Government desire that the Health Officer shall make a special investigation as to the diseases which bring it about.

4. The mortality from each of the chief diseases was below the average for the preceding ten years. *Cholera* prevailed only in sporadic form and was accountable for 28 deaths, equal to a ratio of only ·05 per thousand of population. So far back as 1893, the ratio of mortality from cholera was exactly the same, and, likewise, again in 1899. In 1900 the ratio rose to 1·3, and in the following year to 2·4. There is still much in the behaviour of this disease from year to year which is obscure; but its history in the European and Native Armies of India, as well as amongst the jail population, shows that the mortality caused by it has continued to diminish in proportion as the sanitary conditions under which the troops and prisoners live have improved. Amongst these conditions, purity of water supplies is usually reckoned to have been of chief importance; but others, such as absence of overcrowding, efficient drainage and conservancy, doubtless played their part. That the measures which have proved successful in preventing the recurrence of cholera epidemics amongst the troops and prisoners would be equally successful in preventing their recurrence amongst the general population, there is no reason to doubt. The difficulty lies in the efficient application of these measures; and until the people themselves take a more active share in the sanitation of their towns and villages than they do at present, there is little hope that the difficulty will be speedily overcome.

5. In no city of India is vaccination so efficiently carried out as in the City of Madras, and, as a result, in no city of India is the mortality from small-pox so low. The death-rate from small-pox, calculated on the seven fatal cases which occurred during the calendar year, was only 0·01, and the average death-rate for the previous ten years only 0·1. Of primary vaccination operations during the season 1903-04, there was an increase both in number and percentage of successful cases. On the other hand, re-vaccination operations decreased from 10,411 in the previous year to 7,440 during the year under report. The character of the season's work can be at once estimated from the circumstance that, of a total of 22,622 individuals who underwent primary vaccination, no fewer than 17,036 were children under one year of age. The season's report on vaccination is subjected to a searching analysis by the Government. Instructions are given for the correction of defects, and suggestions made with the object of securing more strict attention to the rules requiring vaccinated children to be brought to the vaccine depôts for inspection. To check the evasion of vaccination through abuse of the plea of ill-health, it is suggested that the Health Officer should occasionally inspect children whose vaccination has been postponed on account of illness, and satisfy himself of the necessity for the further postponement of the operation. It is pointed out that the combination of cases of primary vaccination with those of re-vaccination, in estimating the percentage of success resulting from the use of different kinds of vaccine lymph, is "misleading and without value." Of the comparatively small number of cases of primary vaccination in which lanoline lymph was used, all proved successful; next comes lymph applied direct from calf to arm, which yielded a percentage of 99·84 successful cases; and, lastly, glycerine lymph, with the slightly lower percentage of 99·35.

6. The City of Madras continued to enjoy the same remarkable immunity from *plague* as in the other years succeeding the first appearance of the disease in Bombay towards the end of 1896. During the year under report, only nine cases of plague occurred in the city, all of

them imported, and of these eight were fatal. The passport system which, as carried out in Madras, has hitherto proved so effectual in preventing the spread of infection by imported cases of plague, continues in force. Moreover, "a very considerable amount of assistance in connection with the detection of actual or suspected cases of plague was received from the public during the year."

7. The high rate of mortality which continues to be recorded from year to year amongst the inhabitants of Madras, and especially amongst its infant population, is acknowledged to be due to the serious insanitary conditions still prevailing in some divisions of the city. In no one of the wards does the death-rate fall below 30 per thousand of population, whilst in some it exceeds 40. The drainage scheme, which, according to the revised estimate, will cost not far short of fifty lakhs of rupees, is in process of execution; but the Government is not satisfied that the undertaking is being pushed forward with all the diligence which the circumstances seem to require. The number of public latrines with which the town is provided is pronounced to be quite inadequate; only one was added during the year to the number already in existence, making up the total to 226. In the absence of sufficient latrine accommodation the soil of the inhabited site, becoming more and more polluted, will remain a source of danger to the public health long after the deficiency of latrines has been made good.

5th June, 1905.

No. 13.

Memorandum by the Army Sanitary Commission on the Administration Report of the Municipal Commissioner of Bombay for the year 1903–04.

The previous year was considered by the Health Officer to be unique in the history of plague in Bombay City. The number of deaths attributed to that disease was lower than in any year since 1897, and accompanying this decrease in the mortality from plague, there was a fall in the death-rate from all causes. But the hopes of continued improvement in the health of the city, which these figures may have given rise to, have not been realised. The death-rate from plague, which had been 17·80 in 1902, has risen to 26·78 per thousand of population in the year under report, whilst the death-rate from all causes has arisen from 62·38 to 65·09.

2. The *birth-rate* of the year has moved in a direction opposite from that of the death-rate, having fallen whilst the latter has risen. This fall the Health Officer attributes "to the fact "that a large number of people had left Bombay, during the first five months of the year, owing "to the scare of plague, the mortality from which was very great during those months." Consequent upon the improvements in birth registration introduced by the Health Officer, although the births fell short of the number recorded in the preceding year by 1,224, they exceeded the average of the preceding five years by 3,332. The proportion of the still-born children to children born alive continues to be much higher in Bombay than in either of the other two presidency towns. In the year under report rather more than eleven children were still-born to every hundred born alive.

3. Of the *death-rate* of 65·09 from all causes, plague of itself was responsible for 26·78. Small-pox and measles were, likewise, much more fatal than in the preceding year. On the other hand, the deaths ascribed to fevers fell to, approximately, half the number recorded in 1902, in the case of those classed as enteric and malarial; whilst from relapsing fever the decrease was still greater, only 167 deaths having been attributed to it against 651 in the previous year. The infant mortality, although slightly less than in the previous year, was still excessive. The death-rate amongst infants was 532·29 per 1.000 births. In one of the wards of the city, Tarwadi, 423 children were born alive, and 367 deaths of children under one year of age registered, giving a death-rate of no less than 867·6 per thousand. The diseases to which the high infant mortality was chiefly due were respiratory affections and debility. To debility alone were ascribed no fewer than 2,570 deaths of children under one year of age; and of these over two thousand took place within thirty days of the time of birth. There need be little hesitation in assuming that in the case of the majority of these deaths, the "debility" assigned as the cause was due to insufficient or unsuitable nourishment, together with the absence of the careful nursing which infants need. Small-pox and measles, between them, accounted for 877 deaths of infants during the year, the former, a preventable disease, causing 436 of this total.

4. The epidemic of *plague*, so far from showing signs of abating, was more severe than in the previous year. In the year under report, 23,344 attacks, followed by 20,788 deaths, were recorded, against 16,423 attacks and 13,288 deaths in the previous year. The mortality from it continued to increase, as usual, from January until the end of March, after which it declined. The sanitary evils, which, in Bombay City, are believed specially to favour the development and spread of plague, are again described, and measures for their abatement recommended by the Health Officer, who continues: "As, however, these improvements in the sanitation of the City "will be gradual, I propose, if necessary, to ask for an increased staff of scavengers, carts, "*halalkores*, drain cleaners and gully flushing engines, and disinfectants, and as soon as the "rains cease to systematically deal with every area in which plague is likely to occur. Every "house which is overcrowded and badly lighted or ventilated will be improved. By these means

"we shall be able to determine the relation of filthy and overcrowded areas to disease." Regarding the work of the Plague Commission, appointed in 1898 to inquire into the cause, &c., of the disease, Dr. Turner, whilst admitting the published Report of the Commission to comprise much that is of value, adds: "But the actual results so far as controlling the disease or throwing "any light as to its origin, its methods of infection and measures to prevent its spread in India, "have been practically *nil*, as is instanced by the virulence of the disease during the last year "in India and Hong-Kong." He urges the need for subjecting plague to further scientific research, and outlines the direction which, in his opinion, this should take.

5. Since *plague* first secured a footing in Bombay City towards the end of 1896, the destructive effects wrought by it have been of so impressive a character, compared with those caused by the other diseases with which the people had become familiar, that the latter are apt to have less attention given to them. During the year under report, 1,477 deaths were caused by small-pox a disease acknowledged to be preventable by vaccination. It is shown by the records of mortality in the Presidency Town of Madras that, under an efficient system of vaccination, the prevalence of small-pox may be so reduced as to cease to be a serious danger to life. The Health Officer is of opinion that the work of the Vaccination Department in Bombay City "leaves much to be desired," and that stricter measures should be taken to enforce it. The heavy loss of life due to small-pox during the year gives much weight to this opinion. If the control of vaccination in Bombay City, hitherto entrusted to the Provincial Sanitary Department, were transferred to the Health Officer, who is constantly present and in a position promptly to detect and defeat attempts at evasion of the bye-laws regarding vaccination, it is probable that it would be more efficient.

6. Bombay enjoyed marked immunity from *cholera*, only 17 deaths having been ascribed to that disease during the year, whilst the mortality from *enteric* and *malarial fevers* fell to about half that recorded in the preceding year. The decrease in the number of deaths from malarial fever, including ague and remittent fever, is remarkable. In the previous year these deaths numbered 4,429, whereas in the year under report they numbered only 2,288. But it is not to be inferred from these figures that fever was only half as fatal in the year under report as during its predecessor. In remarking that the deaths from fever were much fewer than in any of the previous years since 1894, the Health Officer goes on to say: "This is due to the accurate "registration of the causes of deaths, as every death is carefully enquired into by the District "Registrar, and in many instances certificates from the medical men certifying the causes of "death are received, thus a more accurate diagnosis is obtained." It would thus appear that the marked decrease in the mortality attributed to fever is largely, if not altogether, due to more correct diagnosis of the causes of death, following upon the improved system of registration of vital statistics introduced by the Health Officer. It is worthy of note that the number of cases of enteric fever, in the returns, has decreased in almost exactly the same proportion as the number of deaths from malarial fevers. Whilst the deaths from enteric fever decreased from 89 in 1902 to 45 in the year under report, those from malarial fevers decreased from 4,429 to 2,288. It is not stated if the cause of the decrease in the number of deaths from enteric fever was due, as in the case of malarial fevers, to more accurate diagnosis, but the similar and simultaneous decrease in the mortality from both of these types of fever might suggest such an explanation.

7. There has been a notable decrease in the mortality due to *phthisis*. The deaths from this cause were fewer than in the preceding year by 1,115, and fewer than the average for the past five years by 3,223. The returns show that the time of life at which males are most liable to die of phthisis in Bombay is that between the twentieth and thirtieth years of their age, and in the case of females between the twentieth and twenty-fifth years. The death-rate from phthisis among females was more than double that among males. All rooms in which deaths from phthisis occur are disinfected, mostly by means of perchloride of mercury solution; but "light is said to be the most natural important disinfectant of the tubercle bacillus; but this," the Health Officer remarks, "is a blessing hard to obtain in the majority of our ill-ventilated "and over-crowded chawls." The measures being adopted with the object of reducing the excessive mortality from this disease in Bombay City appear, from the returns, to be meeting with success; but so long as 80 per cent. of the total population live in tenements of one room with an average of four or five occupants, as stated in the last Census Report, so long will phthisis continue to levy its annual tale of victims.

8. In the section of the Report giving an account of the administration of the Health Department, a list is given of the establishment now employed under the general direction of the Executive Health Officer. Briefly stated, the city is divided into three charges, each directly supervised by its own medical officer, with a subordinate staff of inspectors of various grades. For registration and relief of plague and other infectious diseases, there are 10 qualified medical men, 20 hospital assistants, and 10 nurses. For veterinary work and inspection of animals and milch cattle stables, there are three qualified veterinary surgeons. The labour establishment, consisting of several thousands of men and cattle, is distributed between the three main divisions of the city. During the year, a municipal laboratory was established and a municipal analyst put in charge. Much work of the utmost importance is being done in this laboratory. Of the samples of milk analysed, a large proportion were found to be adulterated with water: 13 of a total of 48 submitted for examination. Such a state of the milk-supply of the city, it is superfluous to observe, cannot fail to injuriously affect the public health, and more especially the health of the infant population, the mortality amongst which is shown by the returns to be excessive. Yet, we read: "At present the Act gives no power to prosecute any one selling "adulterated milk, but when the Act is amended this power should be rigidly enforced."

Dangerous defects in the drainage of the town are again brought under the notice of the Corporation, and suggestions made for their removal. At present, the sullage and night-soil from the house gullies is allowed to percolate into these defective drains, and there to stagnate and soak through into the subsoil. The consequent sewage-logged condition of the subsoil is considered by the Health Officer to be one of the chief causes of ill-health. A perusal of the Report impresses the reader with the conviction that the Sanitary Department of Bombay is being administered with vigour; and that a determined effort is being made, at enormous cost, to free the city from the overwhelming burden of sickness which has borne so heavily on its inhabitants since plague made its appearance amongst them in 1896.

ARTHUR GODLEY,
Under-Secretary of State for India.

REPORT.

The following Report on Sanitary Measures in India during the year 1905 is prepared for presentation to Parliament. It deals with the health of European and Native troops, of prisoners in jails, and of the general population; it also deals with vaccination, medical institutions, including hospitals and dispensaries, medical schools, and lunatic asylums, and with sanitation.

I.—EUROPEAN ARMY.

Sickness and mortality in 1905.

Sickness and Mortality in 1905.—In 1905, as in 1904, there was a marked improvement in the health of the European troops serving in India. The rates of admission to hospital, of constantly sick, of mortality, and of invaliding were the lowest on record. This is the more satisfactory as 52 per cent. of the strength were under 25 years of age, and 25 per cent. had less than one year's service in India. On an average strength of 71,343 the admissions into hospital were in the ratio of 834 per 1,000, against 900 in 1904, while the daily sick-rate fell from 57 to 52, and the death-rate from 10·83 to 10·05 per 1,000. The invaliding ratio (21) was lower by 14 per 1,000. The gain derived from the decrease in the number of men constantly sick alone was equal to the work of 116,435 men for a whole day. The following statement shows the sickness and mortality among European troops in the three Commands and the Secunderabad and Burma Divisions during 1905 and 1904:—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.				
			Admissions.	Constantly Sick.	Deaths.	Invaliding.	Total Loss.
Northern Command ...	1905	18,274	800	49	9·08	20	29
	1904	18,297	881	53	11·15	34	45
Western „ ...	1905	19,537	896	55	11·62	29	41
	1904	19,699	909	60	12·39	44	56
Eastern „ ...	1905	18,983	820	54	10·90	19	30
	1904	18,648	887	59	11·10	31	42
Secunderabad Division	1905	8,389	813	62	8·46	18	26
	1904	8,226	914	62	7·29	44	51
Burma „	1905	3,812	971	54	9·71	15	25
	1904	3,782	1,099	67	9·25	27	36
INDIA	1905	71,343	834	52	10·05	21	31
	1904	71,083	900	57	10·83	35	46

It will be seen from the above statement that the Northern Command had the lowest admission and constantly-sick rates, and that the Secunderabad Division had the highest sick-rate and lowest death-rate, and the Western Command the highest death-rate. In regard to mortality, there was an improvement in all the Commands. The Quetta Division had the highest admission-rate (1,024) and constantly-sick-rate (60), and the Peshawar came next, though in 1904 it had the lowest rates. The Rawalpindi and Lahore Divisions were the healthiest in 1905.

The chief causes of sickness were, as usual, venereal diseases and ague, the former yielding a ratio of 154 per 1,000 against 198 in 1904, and the latter 111 per 1,000 against 174. For the preceding decennium the admission-rate for venereal diseases had averaged 386, and for ague, 311 per 1,000. The decline in sickness is, as shown below, partly due to the new procedure in the treatment and statistical record of these diseases, and not exclusively to their diminished prevalence. Thirty-two per cent. of the total sickness resulted from these two causes. There was increased sickness from simple continued fever, influenza, and small-pox. Enteric fever and hepatic abscess were, as usual, the chief causes of mortality, but the death-rate from the former was only 2·99, as against 3·76 in 1904. Thirty per cent. of the total deaths were due to enteric fever, and 12 per cent. to hepatic abscess. Mortality from heat-stroke, pneumonia, and dysentery was higher. The chief causes of invaliding were debility, ague, tubercle of the lungs, heart complaints, and syphilis, these accounting altogether for over two-fifths of the total invaliding. The highest death-ratio was among men over 40 years of age and men of over 10 years' service. The admission-rate of European troops was nearly 40 per cent. greater than that of

native troops, while their constantly-sick rate was twice as high. The European death-rate was 10·05 and the native 8·09 per mille.

The following table shows the sickness and mortality among the European troops according to geographical groups:—

Groups.	Average Strength.	Ratio per 1,000 of Average Strength.		
		Admissions.	Constantly Sick.	Deaths.
Burma Coast and Bay Islands	1,259	1,221	52	7·15
Burma Inland	2,063	823	51	8·73

Hill Convalescent Depôts and Sanitaria ...	3,512	819	60	9·11
INDIA	71,343	834	52	10·05

Of the above 12 groups, four returned a higher admission-rate than that for the European Army as a whole, and in six groups the death-rate was higher. The most unhealthy group, judged by the admission-rate, was the Burma Coast, with a rate of 1,221 per 1,000. This group and Bengal and Orissa are always among the most unhealthy. Of the stations with a strength of over 1,000, the highest death-rates were those of Jhansi (21·03), Peshawar (18·04), Meerut (16·99), and Agra (16·58).

Venereal Diseases.—Venereal diseases ranked first in the list of causes of admission to hospital. They were the cause of 18·4 per cent. of the total sickness during 1905, and of 5·5 per cent. of the invaliding in the European Army. The admission-rate per 1,000 was 154, a lower rate than had been recorded for 30 years, and less than one-third of the maximum rate of 522 recorded in 1895. The reduction in the rates for 1905 is partly due to changes in the methods of classification, diagnosis, treatment, and statistical record, especially as regards syphilis, for which the admission-rate was only 35·6 in 1905 as against 49·1 per mille in 1904 and 79·4 in 1903, largely owing to the non-recording of patients who develop secondary symptoms after previous admission for primary syphilis and to the out-patient system of treatment. At the same time there has been a real reduction in the prevalence of these diseases. The recent steady and fairly rapid fall in the death and invaliding-rates points to the good results of more prolonged and thorough treatment. Of the Commands the highest admission-rate, viz., 166, was in the Eastern Command, followed closely by the Western Command, 155. The Northern Command, as usual, suffered least; the Burma Division most, with 207 per mille. The rates at certain stations were very high, *e.g.*, Maymyo (338), Rangoon (254), Bombay (265), Fort William (284), Bellary (264), and Madras (267). The number of men constantly sick in hospital from these diseases was 1,089 against 1,241 in the previous year; and the average stay of a case in hospital was about 36 days. The total loss of service thus involved amounted to 397,584 days. The deaths from these diseases numbered 13 (or 0·18 per mille), and the invalidings 83 (1·16 per mille), against 15 and 199 respectively in 1904. The diseases are largely due to the youth and ignorance of the soldiers and the difficulty of controlling infection outside the cantonments, and especially on the line of march between stations. Measures of prevention are taken by officers of all ranks, the principal being rigid medical inspection to detect disease, enlightenment of the soldier as to the dangers of the diseases, and endeavours to encourage games and other means of spending leisure hours pleasantly.

Fevers.—In 1905 the autumn rainfall was abnormally small, and there was exceptionally little malaria. The admission-rate from intermittent fever was less than in 1904, viz., 111 against 174, and the death-rate fell from 0·24 in 1904 to 0·11 per 1,000. The Western Command had by far the highest admission-rate, the Mhow

and Poona Divisions being especially affected. Ague accounted for 13 per cent. of the sickness from all causes as against 19 per cent. in 1904. The rate has fallen steadily since 1901, but though the decline may be due partly to more effective prophylaxis and treatment, it may also be partly owing to the classification of more cases as simple-continued fever, the admission-rate for which was greatly increased in 1904 and 1905. The admission-rates for 1901 and 1902 were 293 and 247 respectively, and the decennial rate for 1891 to 1900 was 346 per 1,000. Special reports by medical officers confirm the view that the "benign" forms of malarial fever greatly preponderate in India over the so-called "malignant" forms. A careful system of quinine treatment, isolation of malarial patients, and anti-mosquito operations were among the chief measures adopted to check malaria during the year.

The admissions for *enteric fever* were 1,146, or 16·1 per 1,000 of strength, as against 1,395, or 19·6, in 1904, and the deaths were 213 against 267, or a death-rate of 2·99 against 3·76. The constantly sick-rate was 220·5 against 256·2. The average duration of a case was 70 days, against 68 in 1904, and the total loss of service was 80,482 days against 93,769. In the Commands the sickness from enteric fever was approximately the same. Among the stations with an average strength of over 1,000 Meerut returned a death-rate of 11·68, Peshawar, 7·82, Mhow 7·09, and Jhansi, 6·69. As usual, young and unacclimatised soldiers were the chief sufferers. Among those from 20 to 25 years of age the death-rate was 4·32 per 1,000 against 5·45 in 1904, while among men between 25 and 30 and from 30 to 35 the mortality was 2·34 and 1·14 per 1,000 respectively. Of the 213 deaths from enteric fever, 70 per cent. occurred among men between 20 and 25, and 25 per cent. among men between 25 and 30. Among men of less than one year's residence in India the death-rate was 4·34 per 1,000, among men between one and two years' service 3·34, and among men between two and three years' service 3·24. During recent years the admission-rates for the higher age periods have tended to rise. Patients are now kept in hospital longer than formerly. The diminution of the disease is largely due to the prophylactic measures now in force, especially those aiming at limiting infection by contact, *e.g.*, segregation of new arrivals, early diagnosis and isolation of cases, attempts to disinfect the convalescent, and disinfection of latrines, barracks, and clothing. A standing Committee has been formed (July 1906) to investigate and advise on the incidence of enteric fever in India and its prophylaxis.

Abscess of the Liver.—From hepatic abscess there were 92 deaths, giving a ratio of 1·18 per 1,000 of strength, against 97 deaths and 1·36 per 1,000 in 1903. The mortality was far higher in the Western and Eastern than in the Northern Command.

Other Diseases.—Cholera was less prevalent, and only 10 cases were recorded with 9 deaths, against 11 fatal cases in 1904, and 57 in 1903.

Small-pox was twice as prevalent as in 1904, 99 cases with 1 death having occurred, against 49 cases and 4 deaths in 1904. Poona and Mhow were the stations chiefly affected.

The admission and death-rates from dysentery have declined in recent years, but they increased slightly in 1905, when the admission-ratio was 13·4 per 1,000 against 12·6 in 1904. The mortality was 0·46 per 1,000 against 0·42 in 1904. As regards Commands the highest place was occupied by the Western.

There were 13 cases of plague and 4 deaths, against 2 cases and no death in 1904. The total included 7 cases with 2 deaths at Aden.

Influenza was especially prevalent, the admission-rate being 14·2 per mille as against 4·9 in 1904. Peshawar was the station chiefly affected.

As regards tubercle of the lungs there were slightly lower admission and death-rates. It was most fatal in the Poona Division.

Invaliding.—The loss by invaliding during 1905 amounted to 1,508 men, equal to 21·24 per 1,000 of strength, against 2,507 or 35·27 in 1904. The invaliding rates ranged from 28·61 in the Western Command to 14·95 in the Burma Division. The most striking decreases in invaliding were in ague, tubercle of the lungs, and syphilis. Of the 116 invalided from tubercle of the lungs 98 were under 30 years of age. The number of invalidings for syphilis was 75, and for debility 152. As regards the influence of age and length of residence in India upon invalidings, 47 per cent. of the total number invalided were under 25 years of age and 82 per cent. were under 30, while 25 per cent. were of less than two years' service, and 65 per cent. were of less than five years' service.

II.—NATIVE ARMY.

Sickness and Mortality in 1905.—The health of the Native Army during 1905 was exceptionally good. The death-rate and constantly-sick-rate were the lowest on record, but the admission-rate was slightly higher than in 1904. The low death-rate is all the more noteworthy, as out of a total of 998 deaths, 185 occurred through the collapse of buildings at Dharmsala during the earthquake. The invaliding-rate was lower.

The ratios of sickness and mortality during 1905 and the previous year were as follows:—

Commands.		Average Strength.	Ratio per 1,000 of Average Strength.		
			Admissions.	Constantly Sick.	Deaths.
Northern Command	1905	36,696	652	26	12·92
	1904	40,293	609	23	7·70
Western „	1905	33,932	602	23	6·60
	1904	34,894	654	26	7·97
Eastern „	1905	21,823	572	23	6·42
	1904	22,777	545	21	6·23
Secunderabad Division	1905	11,794	466	19	5·77
	1904	14,290	437	19	6·79
Burma „	1905	4,793	614	26	6·47
	1904	6,401	564	23	6·89
INDIA	1905	123,434	607	23	8·09
	1904	124,055	603	24	8·46

In 1905 the Northern was the most unhealthy of the Commands.

The following statement gives the principal statistics of the Native Army, arranged in geographical groups, for 1905:—

Groups.	Average Strength.	Ratio per 1.000 of Average Strength.		
		Admissions.	Constantly Sick.	Deaths.
Burma Coast and Bay Islands	1,195	625	24	4·18
Burma, Inland	2,916	539	22	5·14
Assam	949	751	26	4·21
Bengal and Orissa...	2,558	877	27	5·08
Gangetic Plain and Chutia-Nagpur	7,046	506	18	5·96
Upper Sub-Himalayan	16,649	512	23	6·97
North-Western Frontier, Indus Valley, and North-Western Rajputana	17,946	664	25	7·02
South-Eastern Rajputana, Central India, and Gujarat	13,651	588	21	6·89
Deccan	15,977	445	18	4·19
Western Coast	1,978	606	29	17·69
Southern India	5,967	552	21	5·87
Hill Stations	20,224	729	31	18·05
INDIA	123,434	607	23	8·09

The chief causes of sickness were ague, dysentery, venereal diseases, and simple continued fever, pneumonia and other respiratory diseases, while pneumonia, remittent fever, and tubercle of the lungs were the chief causes of mortality.

In six of the 12 groups the constantly-sick-rate was higher than that for the whole Native Army, and in two the mortality was greater. The highest mortality was recorded by the Hill Stations group, owing to the catastrophe at Dharmsala.

Out of 36 stations with an average strength of over 1,000 in 1905, there was only one in which the sickness and mortality were heavy. At Dera Ismail Khan the admission and death-rates were 967·0 and 16·52 respectively. Most of the deaths were due to pneumonia. Comparatively low hill regions near the foot of mountain ranges are found to be unhealthy as regards both sickness and mortality. In hill stations above 5,000 feet the health of native troops compared unfavourably with that of those located in the plains.

The native troops suffered less than the European troops from influenza, small-pox, enteric fever, simple continued fever, diarrhœa, hepatic affections, and venereal diseases, but more from the other chief causes of sickness, especially dysentery, pneumonia, and plague.

Intermittent Fever.—The chief cause of sickness was, as usual, ague, which contributed 28 per cent. of the total admissions. The admission-rate, however, was only 171 per mille as against 194 in 1904. The Western Command was that principally affected. November, and not, as is usual, October, was the month of greatest prevalence.

Pneumonia.—Pneumonia was, as usual, the chief cause of death in the Native Army, and contributed 23·5 per cent. of the total deaths, the death-rate being 1·90 per 1,000 of average strength, against 2·32 in 1904. From this disease the mortality among the Native soldiers was thrice as great as that among European troops. As invariably happens, it was most prevalent among troops located on the North-West Frontier and in the Indus Valley.

Other Diseases.—There were only 11 cases of cholera with 7 deaths, as against 27 cases and 22 deaths in 1904. The admission and death ratios for enteric fever were only 1·1 and ·28 per mille respectively, as against 16·1 and 2·99 for European troops. Remittent fever accounted for 6·9 per cent. of the total mortality. Admissions for simple continued fever were more than twice as numerous as in 1904, viz., 14·3 against 6·7 per 1,000. There was a decrease of plague among the Native troops. In 1905 there were 79 cases with 46 deaths, as against 187 cases and 111 deaths in 1904. The admission-rate for tubercle of the lungs, which had been rising for many years, declined in 1904 to 3·9 per mille and to 3·1 in 1905. The disease, however, caused 6·2 per cent. of the total mortality. The admission and death-rates for dysentery, viz., 32·5 and ·18 per mille, were among the lowest on record. Venereal diseases accounted for only 19·6 per mille of the sickness. They were nearly eight times as prevalent among European as among Native troops. Their prevalence in the Native Army has declined from 42·5 per mille in 1900 to 19·6 in 1905. The Gurkhas, as usual, suffered most.

Invaliding.—The chief causes of invaliding were debility, tubercle of the lungs, rheumatism, venereal diseases, and ague. The invaliding-rate was 9·02 per 1,000 against 12·98 in 1904, the respective numbers discharged being 1,113 and 1,610.

III.—GENERAL POPULATION.

Meteorology.—The chief meteorological conditions of the year 1905 were the severity and persistency of cold weather till the end of April; the lateness and scantiness of the monsoon rains especially in North-West India, and the consequent high temperature; and the extreme weakness of the retreating monsoon over the greater part of the peninsula. The year, apart from plague, was exceptionally unhealthy, 681,299 more deaths being recorded than in 1904. The mortality from all the principal diseases increased. In all provinces, except Bombay and the Punjab, the death-rate was higher in spite of the great reduction in plague mortality.

Registration of Vital Statistics.—Registration is even now not universal, and it is compulsory only in the towns, where the municipal authorities seldom enforce the bye-law. The figures registered are not generally accurate, and the degree of accuracy differs in the various provinces. The facts are nearly everywhere collected by an unpaid and generally illiterate agency, usually by the police (except in Madras and Coorg). Accurate statistics of the causes of deaths cannot be obtained without a professional agency. It is more difficult, especially in towns, to obtain information about births than about deaths, and hence infantile mortality, which is calculated from the numbers of births and deaths of infants registered during the year, appears excessive. Further, we have to depend on the census population, because the registered returns are too inaccurate to allow of calculations of intercensal populations, with the result that as the decennium advances, rates become unduly high. Actuarial reviews of the returns of the last three censuses show that the registered birth and death rates are understated. As registration improves, the registered rates will approximate the calculated rates. A progressive increase in the registered death-rates cannot, therefore, be regarded as proving the impoverishment of the mass of the Indian people. The high Indian birth-rate is due, not to exceptional fertility, but to the large proportion of married women. The high infantile death-rate is largely due to the weakness of the children of youthful parents.

Births and Deaths.—The mean birth-rate of the population under registration, 223,124,252, was 39·13 per 1,000, against 40·86 in 1904, the birth-rates of the larger provinces ranging from 54·02 per 1,000 of population in the Central Provinces and Berar, where the birth-rates of recent years have been extraordinarily high, to 32·0 in Madras. The mean death-rate for the whole of India was 35·96 per 1,000 against 32·86 in 1904, the death-rates ranging in the various provinces from 47·55 in the Punjab to 21·4 in Madras. In the Central Provinces and Berar the birth-rate exceeded the death-rate by 16·81 per 1,000. In the Punjab and the United Provinces the birth-rate fell short of the death-rate by 3·2 and 2·76 per 1,000 respectively. The infantile death-rate ranged from 301·29 in the Central Provinces and Berar to 162·99 in Madras.

Chief Diseases.—Of the chief diseases cholera was most fatal in Eastern Bengal and Assam (death-rate 4·77 per 1,000), Bengal (2·93), and the United Provinces (2·55). The total mortality from cholera rose from 192,835 to 441,786. Small-pox was present in every province, especially in Lower Burma (death-rate 1·01) and Bombay (·92), and the mortality for India generally was 70,963 as against 55,232 in 1904. From fevers the number of deaths was higher than in 1904 by 323,674, the total being 4,417,655. The mortality was greatest in the United Provinces and Bengal, and very low in Madras and Burma. But fever is credited with many deaths really due to other diseases. Deaths from dysentery and diarrhœa rose from 273,459 to 264,124. By far the highest death-rates from these diseases were registered in the Central Provinces (3·02) and Bombay (3·0). The death-rates from respiratory diseases were highest in the Punjab (3·05) and Bombay (2·95). The year 1905 was the tenth of the present epidemic of plague in India. A decrease of 74,793 deaths occurred in the year under notice, the total being 1,069,140 in India as a whole. Of these 334,897 occurred in the Punjab and 383,802 in the United Provinces, the respective rates per 1,000 being 16·65 and 8·05. The disease was practically absent from Eastern Bengal and Assam, Coorg, and the North-West Frontier Province, while in Burma and Madras the mortality from it was relatively low. The mean plague death-rate was 4·17 per 1,000. Females suffered

from plague more than males. An Advisory Committee in England and a Commission in India are investigating the etiology of plague. Investigation tends to show that the rat plays the chief part in the spread of plague, but as there are no effectual means at present of completely destroying rats and rat fleas, the evacuation of houses infected by rats and inoculation appear to be the most effective anti-plague measures.

The deaths from the chief diseases and from all causes in the several British provinces in 1905 were as follows:—

Provinces.	Cholera.		Small-pox.		Fevers.		Dysentery and Diarrhœa.		Plague.		Deaths from all Causes.

* Including statistics for Eastern Bengal. † Excluding statistics for Eastern Bengal. ‡ 12 towns only.

Bengal.

The weather of 1905 was abnormal, and conditions were unhealthy in the reconstituted province of Bengal. The rainfall was excessive and the temperature low early in the year, while the late commencement and early cessation of the monsoon rains entailed a good deal of damage to crops in the last quarter of the year. The birth-rate per 1,000 of the population, viz., 49,891,164, was 39·55. The average birth-rate in rural areas was 40·58 per 1,000 against 24·53 in towns, where low rates are due to disproportionate male populations, defective registration, &c. Registration is not universal, and although it is compulsory in towns, the bye-law is seldom enforced. Among towns Jamalpur had, as usual, the highest birth-rate (65·17).

Owing to a general increase in deaths from the principal diseases the death-rate was 38·53 per 1,000.

As regards infant mortality 216·6 per 1,000 of male and 200·4 per 1,000 of female infants born died during the first year of life. The rates of infant mortality varied from 310 per mille in Calcutta, which, as usual, had the highest mortality, to 131·8 in Darbhanga district. The infant death-rate for Bengal generally was 208·6 per mille. Leaflets in the vernacular are being distributed, containing simple instructions as to the rearing and care of infants, and as to the diet of Indian mothers after child-birth.

Taking the chief diseases seriatim, cholera was more fatal than in the preceding year, the number of deaths being 146,639 or 2·93 per 1,000, against 1·63 in 1904. The disease was present in every district. The district of Gaya suffered most severely and lost 6·63 per 1,000, while of other districts Purnea lost 5·17, Patna 5·0, and Shahabad 4·94. The contamination of wells by surface washings after a heavy rainfall is said to have been the cause of the great prevalence of the disease in Gaya. Among other precautionary measures the disinfection of wells with permanganate of potash was resorted to in 17 districts which suffered from cholera.

Small-pox, after three years of severe prevalence, greatly abated in 1904 and 1905, and the deaths fell in 1905 to 7,213 or 0·14 per 1,000. Puri and Murshidabad were the districts most affected. Out of the total small-pox deaths over 64 per cent. occurred amongst children under ten years of age.

Fever was more prevalent than in the preceding year, the mortality from it amounting to 24·34 per 1,000, against 20·49 in 1904. Over 63 per cent. of the mortality from all causes was due to fever alone, but many diseases are classed inaccurately as "fever." Mortality increased in both urban and rural areas. The highest death-rates were in the districts of Shahabad, Nadia, and Gaya. As bad

drainage is a main cause of sickness a special committee has been appointed to consider the question of drainage. The number of parcels of quinine (each containing 102 packets of seven grains) sold in 1905 was 35,472. Facilities for extending the sale are being increased.

Dysentery and diarrhœa showed a death-rate of ·90 per 1,000. The highest death-rates were recorded in Orissa, where infantile diarrhœa was extremely prevalent, and in the Howrah and Patna districts, where the respective death-rates were 4·29 and 4·19 per 1,000. The mortality was four times as great in urban as in rural areas. A special enquiry has been instituted regarding these diseases.

Plague during 1905 raged with great virulence, and carried off 126,084 persons, equal to a ratio of 2·52 per 1,000 of population. The plague death-rates were highest in the Saran and Patna districts, viz., 14·79 and 14·72 per mille respectively. The disease was much more prevalent and fatal in urban than in rural areas, and amongst females than amongst males. The plague mortality in the town of Daudnagar was 65·98 per 1,000. Rat extermination was carried on in many places. The climax of the disease was, as usual, reached in March.

City and Port of Calcutta.

The municipality of Calcutta recorded a birth-rate of 18·44 per 1,000 of population, which is an improvement on the previous year's rate of 17·9, but still far below the actual facts. The death-rate rose from 32·2 to 37·95 per 1,000. Excluding plague deaths the ratio is only 29·26. Plague showed an increase from 5·53 to 8·69. As Calcutta has a filtered water supply and a proper sewerage system, the deaths from cholera and malaria are much below those in other Bengal towns. Plague seems to be equally severe in Calcutta and the mofussil towns, while respiratory diseases appear to cause fewer deaths in the latter because they are reported as fever, &c. Small-pox occurred in severe form and the death-rate therefrom was ·32 per 1,000. The relative healthiness of Calcutta is ascribed to its comparative freedom from malarial fever, its fever death-rate in 1905 being only 5·13 as against 24·34 for Bengal as a whole.

A total of 20,339 European seamen arrived in the port of Calcutta during 1904, giving a daily average population of 1,114. There were 19 deaths, including one from cholera. Among the native floating population, estimated at 29,768, there were 128 deaths (a ratio of 4·29 per 1,000 as against 3·76 in 1903), including 33 from cholera and 20 from fever.

Eastern Bengal and Assam.

The weather was cold early in the year, while later on there was excessive rain, with floods, in some districts. The climatic conditions were, therefore, unfavourable to health. In the area under registration, with a population of 29,812,735, the births represented a ratio of 39·37 per 1,000. As usual, Goalpara had the highest district birth-rate (50·70). The registered death-rate, owing largely to the cholera epidemic, reached 35·06 per 1,000. The infant death-rate was 203·45 per 1,000.

The death-rate from cholera rose to 4·77 per 1,000, the number of deaths being 142,312. The disease raged in most of the districts bordering on the lower reaches of the Brahmaputra and Ganges and the upper portion of the Meghna, and its severity is attributed to the unusually high floods of the year. The mortality from cholera among the tea-garden coolies was 2·14 per mille.

The mortality from small-pox was low, giving a rate of only 0·15 per 1,000, the decennial rate being 0·23. The disease was most prevalent in the Kamrup district, where the death-rate was 2·78 per 1,000.

The death-rate from fevers rose slightly. In 1905 it was 23·68 per 1,000, the mortality being highest, as usual, in the Dinajpur district (36·15). From *kala-azar* 3,030 deaths were recorded. There has been a steady decrease in the mortality under this head since 1897, in which year there were 18,597 deaths from the disease, but it is believed to be more widespread than the returns indicate. A special report on *kala-azar* shows that it is distinct from malarial fever.

From dysentery and diarrhœa the death-rate was 0·85 per mille. Of the individual districts the mortality was highest in Lakhimpur (6·80) and Sibsagar (4·57), in which the tea-garden population bears a higher proportion to the total than in other districts of the Assam Valley.

Plague caused 6 deaths, all imported cases.

United Provinces of Agra and Oudh.

Climatic conditions were unfavourable to health in the United Provinces of Agra and Oudh in 1905. The birth-rate fell to 41·24 per 1,000, which was below normal. The highest district rate was 52·59 in Jhansi, and the lowest 27·86 in

Dehra Dun. The death-rate was higher than in any other province, except the Punjab. The number of registered deaths rose from 654,949 or 34·7 per 1,000 in 1904 to 2,098,300, or 44·0, in 1905, the district rates varying from 91·01 in Muttra (where the plague death-rate was 62·64), and 66·58 in Sultanpur (where the cholera death-rate was 25·30) to 26·12 in Almora, which was free from plague and cholera. The mean rural death-rate was 43·26 against 53·64 in towns, in many of which plague was severe. The infant death-rate was 263 per 1,000.

Cholera deaths rose from 6,617 or ·14 per 1,000 in 1904 to 121,790 or 2·55 in 1905. The highest mortality was in Sultanpur district (25·30 per mille), and five others were severely affected.

From small-pox the deaths fell from 6,998, or 0·15, in 1904, about the normal rate, to 3,273, or 0·07 in 1905. Eight districts were practically free from the disease.

The United Provinces had the highest provincial death-rate from fevers. The deaths attributed to fever rose from 1,141,029 or 23·92 per 1,000 in 1904 to 1,284,164, or 26·92, in 1905. The highest urban death-rate as in 1904 was in Brindaban (Muttra), while Saharanpur and Ghazipur had the highest district rates. Increased efforts are being made to improve surface drainage, to fill up hollows, and to bring quinine more generally within the reach of the poorer classes. In 1905 643,668 pice packets of quinine were sold, mostly by post offices.

The number of deaths recorded under dysentery and diarrhœa, 26,532 (·56 per 1,000) was somewhat higher than in 1904, but below the quinquennial mean. As usual, Garhwal headed the districts with a death-rate of 11·39, followed by Almora (4·20) and Ballia (3·07). The urban death-rate was five times the rural.

The mortality from plague was the highest on record, and was more than twice as great as in the previous year, the total being 383,802 or 8·05 per 1,000 as compared with 179,082 or 3·75 in 1904. The highest rates recorded in the districts were 62·64 in Muttra, 22·03 in Ghazipur, 19·94 in Allahabad, and 19·08 in Agra. Only one district (Almora) returned no death from plague. Of towns Kiratpur (Bijnor) had the highest death-rate (71·82).

Punjab.

Weather conditions in the Punjab were unfavourable, and it was the unhealthiest province in India in 1905 as in 1902, 1903, and 1904. Plague again dominated the vital statistics. Nevertheless, the mortality was below that of 1904. The birth-rate was 44·4 per 1,000 of population, or 3·0 more than that recorded in the previous year and about 4·0 above the quinquennial mean. According to districts the birth-rates ranged from 67·2 in Lyallpur to 21·4 in Simla. The death-rate was 47·6 as against 49·1 in the previous year. Among the districts Rohtak had the highest death-rate, 78·5 per 1,000. In Kangra, where 1,374 persons lost their lives in the great earthquake of April, 1905, the death-rate was 306·6, while in Dharmsala, which also suffered heavily, the rate was 90·02. The infant mortality, 235 per 1,000 births, was about normal.

In 1904 cholera was more rife than in 1904, but did not prevail in severe epidemic form, and was confined to a few localities. The deaths numbered 2,197, equal to 0·11 per 1,000. No less than 1,624 of the total deaths were in Lahore district. The highest urban death-rate was 13·78 per mille in Shujabad (Multan).

The mortality from small-pox was 4,723, or ·23 per 1,000, against 9,624 or ·48 per 1,000 in 1904. Ludhiana district was the chief sufferer with a death-rate of ·89 per 1,000, and Kangra, which is the best vaccinated district, had as usual the lowest rate.

From fevers the death-rate was 18·40 per 1,000 in 1905, or 6·65 below the quinquennial mean. Delhi district recorded the highest mortality, viz., 24·74 per 1,000. It is believed that many deaths really due to plague, respiratory diseases, &c., were classed as fevers. Quinine was as usual distributed gratuitously in many of the districts.

The death-rate from dysentery and diarrhœa was above that of 1904, though below normal. The highest rate was in Simla district (2·25). The urban death-rate was three times the normal.

Plague was not as widespread or as fatal in 1904. The deaths fell from 396,357, or 19·71 per 1,000, in 1904 to 334,897, or 16·65, in 1905. At first the disease was very virulent, but it declined later. In ten districts the death-rate was above 20 per 1,000. The large towns have suffered but little. Among districts Rohtak lost 52·6 per 1,000 of its population from the disease, Gurgaon, 40·9, Ludhiana 34·2, Amritsar,

34·0 and Lahore 29·7. The female plague death-rate is higher than the male. Infants and aged persons are markedly immune. The attitude of the people towards the disease is one of apathy, though evacuation is resorted to in many districts. Disinfection, inoculation, and rat destruction have been adopted as preventive measures.

North-West Frontier Province.

In the North-West Frontier Province the birth-rate rose to 35·4 per 1,000 in 1905 from 34·9 in 1904 (3·0 above the quinquennial mean), and the district rates ranged from 43·3 in Kohat to 31·7 in Hazara. The number of male births registered is much greater than that of females, A special enquiry appears to show that although registration is carelessly performed, the proportion of male to female births is really very high. The death-rate fell from 28·6 to 26·8 per 1,000. The year 1905 cannot be considered a healthy one, as the rate in the previous five years had averaged only 25·5. The infant mortality was 198 per 1,000.

In 1904 there was only one death from cholera, but in 1905 303 deaths were recorded owing to an epidemic in the Hazara district. From small-pox the death-rate fell from ·78 to ·29 per 1,000. The death-rate from fevers, 20·69 per 1,000, was lower than in 1904, but above the quinquennial mean, Peshawar district, as usual, being that most affected. The mortality from dysentery and diarrhœa was slightly lower. There was no indigenous plague in the province.

Burma.

The registration of vital statistics has hitherto been backward in Burma, but improvements are in progress. The weather conditions were generally unhealthy in 1905. In Lower Burma the birth-rate in 1905 was 34·34 per 1,000 against 32·71 in the preceding year. In Upper Burma the registration of births is confined to twelve towns, and the average birth-rate was 34·91 against 35·05 in 1904. In Lower Burma the death-rate rose from 22·36 in 1904 to 24·93, and in Upper Burma from 18·69 per 1,000 to 22·46. The high infant mortality rate is attributed to defective midwifery and insanitary conditions.

Cholera was prevalent during the year. The death-rate was ·63 per 1,000. The disease caused a death-rate of 4·11 per 1,000 in Mergui.

Small-pox was much more prevalent in Burma than in the previous year. The death-rate was 1·21 per 1,000 in Lower Burma as against ·24 in 1904. In Upper Burma, the increase was slight, the death-rate being ·18 as against ·17. In Rangoon the rate was as high as 2·98.

Fever as usual was the chief cause of death in the province, but the mortality was below normal. In Lower Burma the deaths were in the proportion of 8·97 per 1,000 against 9·91 in 1904, and in Upper Burma 6·76 against 7·05. In Akyab district the mortality rate was 23·14. With a view to the prevention of fever systematic measures were carried out generally for the destruction of mosquitoes, and more radical methods of prevention by drainage, &c., are contemplated. The people show little appreciation of quinine, the demand for which is small.

The death-rate from dysentery and diarrhœa in Lower Burma was 1·43 per 1,000 against 1·27 in 1904, and in Upper Burma the urban was ·60 and the rural ·43. The urban areas of Lower Burma suffer most. The rates for Rangoon, Bassein, and Thayetmyo were 5·09, 5·21, and 7·58 per 1,000 respectively.

There was no case of indigenous plague up till the end of 1904, but indigenous plague was discovered at Rangoon in February, 1905, and during the year there were 3,692 deaths in the province, including 2,468 in Rangoon, which had a death-rate of 9·79 per 1,000. Segregation of patients, surveillance of contacts, evacuation of infected villages, disinfection, inoculation, rat-killing, and provision of facilities for inoculation have been the principal anti-plague measures, and they met with considerable success.

Central Provinces and Berar.

The year was unhealthy, owing to delayed and heavy rainfall after a dry year, and influenza, malarial fevers, and bowel complaints were rife. The birth-rate in 1905 was 54·02 per 1,000 of population against 53·19 in 1904. In Yeotmal district the birth-rate was 61·24 per 1,000. All the districts registered comparatively high birth-rates. The death-rate was 37·21 per 1,000 as against 32·06 in 1904. The highest district death-rates were in Burhanpur (54·80) and Buldara (50·08). The infant death-rate was 301·29 among males and 270·94 among females per 1,000 born, an exceptionally high birth-rate, ignorance, neglect, insanitary conditions, and abnormal cold early in the year being responsible for the great mortality.

The number of deaths recorded from cholera declined, the total being 1,217, equal to a ratio of ·10 per 1,000, against ·24 in 1904. The infection is said to have been spread by pilgrims returning from Puri. There was no cholera in Berar.

The mortality from small-pox was greater than in 1904, the number of deaths rising from 2,026 or ·16 to 8,364 or ·70 per 1,000. The largest mortality occurred in the Buldana, Nagpur, and Saugor districts. The mortality among children was very high. The Sanitary Commissioner suspects that many deaths attributed to measles and chicken-pox were due to small-pox.

Fevers were more prevalent in every district, and the death-rate rose from 13·54 per 1,000 in 1904 to 17·43 in 1905. Malarial fevers were especially prevalent after the rains. Something was done during the year in the way of anti-malaria crusades by destroying mosquitoes, filling in pools, &c. The people do not take to quinine as a prophylactic.

The death-rate from dysentery and diarrhœa rose from 2·14 per 1,000 to 3·02, a higher rate than in any other province. The mortality in Berar was much greater than in the Central Provinces. The highest district death-rate was that of Akola in Berar, viz., 10·20 per mille.

Plague was much less prevalent (especially in the Central Provinces) during 1905, and the deaths fell from 42,866, or 3·43 per 1,000, to 12,706, or 1·07. Many deaths ascribed to fevers were probably due to plague. The attitude of the people with regard to plague measures continues to improve; they understand the value of evacuation and disinfection, but inoculation is still unpopular. Rat-killing has been energetically carried on.

Madras.

In the Madras Presidency during 1905 the rainfall was ill-distributed, and food prices rose. The birth-rate per 1,000, viz., 32·0, was the highest yet recorded, except in 1891. The rise was partly due to improved registration. The district rates ranged from 46 in Madras to 24·4 in Nellore. The total number of registered deaths was 786,123, or 21·4 per 1,000, against 22·5 in 1904. In the districts the death-rates ranged from 59·5 in Madras to 16·0 in North Arcot. There was diminished mortality from fever, cholera, and plague. Registration is still defective, though improving.

The number of deaths recorded as due to cholera was 16,888, giving a ratio of 0·5 per 1,000 of population, against 23,109, or 0·6 in 1904. The ratio for 1905 is the lowest since 1895. Owing to timely action taken to combat the disease its progress was checked in most of the municipal towns. The purification of polluted water with permanganate of potash yielded good results in the areas affected.

The death-rate from small-pox fell to 0·5 per 1,000 of population. This coincided with a lower rate in India generally. The mortality was highest in Madura and Bellary districts. In eight municipalities the death-rate exceeded 2·0 per mille. The death-rate of children under 10 was exceptionally high.

Deaths ascribed to fever fell to 265,044, or 7·2 per 1,000, the quinquennial average being 8·2. The mortality recorded under this head represents more than one-third of the total deaths. The highest district ratios were 15·0 per 1,000 in Ganjam and 15·8 in Vizagapatam. Preventive measures against malarial fever are receiving attention.

Dysentery and diarrhœa accounted for practically the same number of deaths as in 1904, the death-rate being 1·4. The heaviest district rate (11·2) was in Madras.

The number of deaths registered under plague fell from 20,125 in 1904 to 5,788 in 1905, representing a mortality of 0·2 per 1,000, which is not a high rate compared with the rates recorded by other provinces. Thirteen districts had no indigenous plague. The disease was most severe in Bellary, where the death-rate was 3·6, equal to 60 per cent. of the total mortality in Madras. As usual, the anti-plague measures adopted were employment of observation and preventive staffs, isolation of patients, segregation of contacts, disinfection of persons, effects, and houses, passporting and surveillance of persons from infected areas, and rat-killing.

Madras City.

In Madras City the birth-rate was 46 per 1,000, which was above the average. The death-rate was 59·5 per 1,000 (the highest in the Presidency) as against 44·2, the average of the previous 5 years. Deaths from all the principal diseases perceptibly increased. The total, 29,351 deaths, included 5,496 from fevers, 5,542 from dysentery and diarrhœa, 3,534 from cholera, which raged in a severe form from July to October, 321 from small-pox, and 22 from plague.

Bombay.

There was a most gratifying decline in the death-rate. The mortality from plague was much smaller than in 1904, while some of the other chief diseases were less fatal. As regards Sind mortality was heavier, owing to malarial fevers and pneumonia, ascribed to the exceptionally cold season.

The registered births numbered 611,173, or 37,421 less than in 1904, and the birth-rate fell from 35·09 to 33·07 per 1,000, which, however, was above the quinquennial mean. Among the districts, Khandesh registered the highest rate, 46·63, followed by Broach, 45·09. The lowest rate was recorded in the Sind district of Thar and Parkar (17·88). Registration of births is unsatisfactory, especially in Sind.

The deaths numbered 588,394, or 31·84 per 1,000, against 764,914, or 41·39 in 1904. The highest district death-rates were 62·33 in Bombay City, and 41·13 in Ahmedabad. In Ahmedabad City the death-rate was 63·43. Infant mortality, 220 per 1,000, was unduly high.

There was comparatively little cholera in the Presidency during 1905, and the death-rate was only 0·29 per mille as against 0·71 in 1904. The only districts much affected were Bijapur, Dharwar, and Belgaum, in which the respective death-rates were 2·02, 1·91, and 1·60 per mille.

From small-pox there were 16,985 deaths, a ratio of 0·92 per 1,000, as against 0·23 in 1904. The mortality was the highest recorded for 27 years. The Bombay and Khandesh districts combined accounted for much more than half the total deaths. About 36 per cent. of the deaths occurred amongst children under one year of age.

The death-rate from fever was only 13·28 per 1,000, or 4·12 below the quinquennial mean. Of the districts Ahmedabad again recorded the highest fever mortality (28·38). Distribution of quinine was adopted.

The deaths ascribed to dysentery and diarrhœa showed a reduction. The death-rate was 3·00 in 1905, as against a quinquennial mean of 4·87.

The deaths from plague were 71,363, or 3·86 per 1,000, or less than one-third of those in 1904, when the death-rate was 12·12 per 1,000. The abatement was shared by nearly all districts, and was greatest in those which have suffered most in the past. The highest district rate (11·68 per 1,000) was in Satara. Karachi town had a death-rate of 24·86. The use of prophylactic serum was extended, and voluntary evacuation of infected localities continued. Among 27,242 persons inoculated plague occurred in only five cases. Although the incidence of the disease was much lighter, its virulence did not decrease, the average case-mortality being 75 per cent.

City and Port of Bombay.

In Bombay City the registered birth-rate was 24·66 per 1,000 in 1905, as against 25·20 in 1904. There was an increase in mortality, the death-rate being 62·3 in 1905 as against 55·0 in 1904. The deaths from plague were 14,171 in 1905 (18·63 per 1,000) as against 13,538 in 1904, and 20,788 in 1903. Cholera caused only 25 deaths. Bombay had the lowest death-rate from fever in the Presidency, 3·41 per 1,000, and the highest from respiratory diseases (12·19).

In Bombay Port 838,953 persons (including crews) were inspected in 1905, and the clothing and bedding of 99,378 of these were disinfected. There were 27 cases of plague, 1 of cholera, 386 of small-pox, and 21 of jigger.

Red Sea Pilgrim Traffic.

Red Sea Pilgrim Traffic.—In September, 1904, the period of detention in observation camps near the port of embarkation was reduced from ten to five days, after which, on passing a satisfactory medical inspection and being disinfected, pilgrims were allowed to proceed. Further changes in the regulations became operative in the season 1906-7. The Haj in 1904-5 was open to any resident in India. All pilgrims were required to embark at Bombay. The year's pilgrimage was smaller than the preceding one; only 12,449 pilgrims sailed from Bombay. Their health was good.

IV.—JAILS.

Sickness and mortality in 1904.

Sickness and Mortality in 1905.—The vital statistics of prisoners in India over a series of years show a general fall in the death-rate, attributed to improvement in the sanitary condition of the jails, though there have been violent fluctuations, ascribed to varying climatic influences. Much is being done for the improvement of jail sanitation and a still further reduction in mortality may be hoped for. The conditions in 1905 were unfavourable to the health of the prison populations, but, in spite of adverse conditions, the statistics show no specially noteworthy ill effects on the health of the prisoners. The mean daily population of the jails in India and Burma (excluding the Andamans) was 91,917, and the admission-rate 647 per 1,000, the constantly-sick-rate 28 per 1,000, and the death-rate 19·23 per 1,000. The admission-rate was the lowest on record. There was an increased death-rate in all provinces except Madras, Bombay, the Punjab, and Burma.

The following statement shows the sickness and mortality among all classes of prisoners in the jails of the various provinces for 1905 as compared with 1904:—

Provinces.	1904.			1905.		
	Ratio per 1,000 of Average Strength.			Ratio per 1,000 of Average Strength.		
	Admissions.	Constantly Sick.	Deaths.	Admissions.	Constantly Sick.	Deaths.
Bengal	883	35	19·6	954	39	24·9
United Provinces of Agra and Oudh.	612	28	14·6	569	27	17·3
Punjab	907	31	19·8	708	26	16·3

India (excluding the Andamans)	676	28	17·6	647	28	19·2

Chief Diseases.—The chief causes of sickness were intermittent fever (admission rate 182 per 1,000), dysentery (82), abscesses, ulcers, and boils (71), and diarrhœa (39), while the chief causes of death were tubercle of the lungs (3·2 per 1,000), dysentery (3·0), and pneumonia (2·3). There was an increase in the incidence of cholera and plague. The death-rate (0·91 per 1,000) from intermittent fever was somewhat higher. In remittent fever there has been a great reduction in the last five years. Bowel complaints, formerly the scourges of Indian jails, are now much less prevalent and deadly, though as causes of mortality they still occupy a foremost place. As regards dysentery, now fully recognised as infectious, the admission-rate has fallen slightly but irregularly in the last 10 years, while the fall in the death-rate has been rapid in recent years, mainly owing to successful treatment. It is, however, still one of the chief causes of mortality, and a special enquiry has been undertaken with regard to its causation, prophylaxis and treatment. Both admission and death-rates for diarrhœa were the lowest on record. Bombay and Bengal had the highest death-rates. The mortality from pneumonia, which is one of the deadliest of jail diseases, tends very gradually to decline, as the result of more efficient ventilation and the treatment of the disease as infectious, and, in spite of the wide diffusion of influenza, the admission and death-rates from pneumonia in 1905 were the lowest on record. In 1904 tubercle of the lungs, though it had declined since 1902, became for the first time a leading cause of mortality. In 1905 there was a considerable increase in the prevalence and fatality of this disease, the jails of Bengal, Eastern Bengal and Assam, and Madras being most affected. There were 40 deaths from cholera as against 31 in 1904, while deaths from small-pox were only four. Although plague was so widespread and fatal during the year there were only 46 deaths from it in the jails owing to the precautions taken. Enteric fever accounted for 15 deaths, and cerebro-spinal fever for only nine deaths.

Bengal. Owing to the unhealthiness of the year the sickness and mortality of the jail population of Bengal were greater than in 1904. The more complete separation of different classes of prisoners has added to the over-crowded condition of some of the prisons. The death-rate among all classes of prisoners (25·3 per 1,000) was much higher than in 1904, when it was 19·5. The admission-rate was 954 per 1,000. The lowest death-rate was in Cuttack Jail (9·4), and the highest in Burdwan (43·3), Purulia (46·6), Chaibassa (44·1), and Midnapore (45·0). The Presidency Jail is about to be demolished. Defects in construction in Midnapore and Purulia Jails are being remedied. Under a new Superintendent the death-rate in Balasore Jail, 79·7 per 1,000 in 1904, has fallen to 22·6 in 1905. The chief causes of sickness were intermittent fever (30·5 per cent. of all admissions) and dysentery and diarrhœa (30·1), and the principal causes of death (26·3 per cent. of all deaths) tubercle of the lungs (16·1), intermittent fever (11·0), and pneumonia (8·5). There was in 1905 a slight decrease in the admissions from intermittent fever. The cases numbered 4,120, while deaths were 39. There were 2,783 cases of dysentery and 93 deaths. The disease is most common in Jessore and Midnapore. Tubercle of the lungs is widespread and shows an increase. The Alipore, Midnapore, Hazaribagh, and Presidency Jails were those most affected. It is proposed to segregate at Berhampore tubercle cases from all jails. A decline in cases of pneumonia is ascribed to better ventilation of sleeping wards. In spite of the wide prevalence of plague the disease attacked only five jails, which recorded 12 cases and 8 deaths.

Eastern Bengal and Assam. The year was unhealthy and among the prisoners in Eastern Bengal and Assam the admission, constantly-sick, and death-rates were all higher than in recent years. The chief causes of sickness were dysentery and ague, and of death, dysentery, tubercle of the lungs, and beri-beri. Among convicts there were 1,830 cases and 47 deaths from dysentery, which was especially severe at Gauhati. The mortality from tubercle was greater than in 1904. There were 11 cases of cholera and 10 deaths. Beri-beri was epidemic at Sylhet and caused 21 deaths. The rate of mortality was very high at Barisal (62·87), Gauhati (58·25), Dibrugarh (57·69), and Sylhet (54·79). Improvements are being effected at Barisal in accommodation and water supply.

United Provinces of Agra and Oudh. The health of the prisoners in the United Provinces of Agra and Oudh was fairly good during the year 1905, although climatic conditions were unfavourable. Influenza was very prevalent. Among all classes of prisoners the admission-rate per 1,000 of average strength was 569 against 612 in 1904, but the death-rate rose to 17·3 from 14·6 per 1,000. In seven of the larger jails there were death-rates of over 30 per 1,000. The higher death-rate was largely due to diseases contracted before admission to jail, but in the jails there were also more plague deaths. The precautions against dysentery taken in Gorakhpur Jail have succeeded. At Benares Jail, where general conditions are satisfactory, the death-rate rose from 10·4 to 33·6 per 1,000, ascribed largely to deaths among old men consequent on the cold winter and spring. The Mirzapur District Jail recorded a rate of only 9·6 per 1,000. The chief cause of sickness was ague (32 per cent. of all admissions). Among the chief causes of death were dysentery (17·3 per cent. of all deaths), tubercle of the lungs (15·4), and dysentery (11·2). There has been a great reduction in the mortality from dysentery in recent years owing to the excellent sanitary conditions under which the prisoners live, to segregation of cases, to disinfection, and to the care which is given to the purity of the water and food supplies. In the majority of the jails there is accommodation for isolating cases of tubercle of the lungs. Pneumonia caused more admissions than in 1904, and 70 as against 59 deaths. In spite of its widespread prevalence in the province, plague accounted for only 26 cases and 19 deaths.

Punjab. The health of the prisoners in the Punjab during 1905 was wonderfully good. The admission-rate declined from 907 to 708 per 1,000, and the death-rate from 19·76 to 16·33. Improvements in the sanitation, accommodation, and ventilation of jails were in active progress. The highest death-rate last year was in the district jail at Lahore, but in 1905 it fell to 10·85 from 36·32 per 1,000. The admission-rate for malaria fell from 342 in 1904 to 259 in 1905, the decline being ascribed chiefly to the maintenance of quinine prophylaxis in the autumn months and treatment of prisoners when admitted to jail. Dysentery, which caused only 6 deaths altogether in 3 jails was completely absent from 25 jails, and its incidence tends to decrease, owing to improved sanitary methods.

Tubercle of the lungs showed an increase from 40 to 50 deaths, while pneumonia caused a mortality of only 28 as against 60 in 1904. These diseases combined were responsible for 44 per cent. of the mortality among convicts. Prevention by prompt detection, isolation, disinfection, &c., is the remedy relied on. Cholera and plague appeared in 3 jails in 1905, but as prompt precautions were taken, only 8 deaths occurred from both causes.

North-West Frontier Province.

The general health of the prisoners in the North-West Frontier Province during 1905 was fairly satisfactory. There was intermittent overcrowding, especially in Kohat and Abbottabad Jails. The death-rate rose from 14·7 to 19·8, which was 7 below that of the free population. Malaria as usual was responsible for most admissions, viz., 380 per 1,000, and it was specially prevalent at Dera Ismail Khan and Kohat. Epidemic influenza caused several deaths in Peshawar Jail. This largely explains the high admission-rate in that jail (42·0 per 1,000). Dysentery was the chief cause of mortality.

Burma.

Among the prison population of Burma the admission and constantly-sick rates were the lowest on record, while the death-rate, which fell from 18·63 per 1,000 in 1904 to 17·01 in 1905, was the third lowest on record. Owing to various improvements the exceptional mortality in Mandalay Jail has been reduced, and the death-rate fell from 79·3 in 1904 to 17·3 per 1,000 in 1905. The central jail at Thayetmyo had the high death-rate of 37·66, dysentery and diarrhœa being very prevalent during the rains and cold weather. The most healthy central jail was the Bassein Central Jail, which recorded a death-rate of 11·92. The chief causes of sickness were abscesses and ague, while the chief causes of death were tubercle of the lungs and dysentery. From dysentery there were 31 deaths as against 32 in 1904. The admissions for tubercle rose from 75 to 88, and the deaths from 36 to 51. The isolation of these cases and their treatment in the open air received the special attention of the medical officers as heretofore. Admissions and deaths from pneumonia, viz., 38 and 12, respectively, were higher than in 1904, when the numbers were 26 and 8.

Central Provinces and Berar.

The improvement in the health of the prisoners in the Central Provinces and Berar Jails noticed in 1903 and 1904 was not maintained during 1905. There was more sickness and the death-rate rose from 12·57 to 15·79. Malarial fevers were as usual the chief cause of sickness and accounted for 30·27 per cent. of the admissions. Tubercle of the lungs, pneumonia, and other respiratory diseases and dysentery were the chief causes of death. The number of admissions (134) and deaths (5) from dysentery was the same as in 1904. From tubercular diseases the mortality was less than in 1904. Although plague was epidemic in so many towns, only one death occurred in the prisons, owing to careful segregation of all admissions from infected localities.

Madras.

The general standard of health was well maintained throughout the year 1905 among the prisoners in the Madras Presidency. The death-rate fell from 16·5 per 1,000 in 1904 to 15·9 in 1905 and was the lowest on record during the last decade. The highest death-rates were in the central jails at Rajahmundry and Cannanore. In the former cholera was epidemic and accounted for most of the deaths. The chief causes of sickness were ague (18·25 per cent. of all admissions) and dysentery (13·63 per cent.), and the chief causes of death were dysentery (19·3 per cent. of all deaths), tubercle of the lungs (14·9 per cent.), pneumonia (9·3 per cent.), and cholera (8·7 per cent.). A special receiving hospital for tubercular diseases has been established at Trichinopoly, and another is in progress for Bellary Central Jail.

Bombay.

There was rather more sickness among the prisoners in the Bombay Presidency during the year 1905, but the death-rate was only 17·45 per 1,000 (the lowest on record) against 19·22 in 1904. Overcrowding occurred in only four jails, and was sometimes relieved by transfers, and by the use of temporary sheds, &c. In the Common Prison, which is structurally defective and was overcrowded, the death-rate reached 55·6 per 1,000. The Thana Jail death-rate fell from 23·39 per 1,000 to 14·83, and although tubercle is still the chief cause of mortality its prevalence has diminished as a result of improvements in treatment and accommodation. A tubercle ward has been established there. The principal cause of sickness in the jails of the Presidency was ague (22·3 per cent. of all admissions) and the chief causes of death pneumonia (17·5 per cent. of all deaths) and tubercle of the lungs (13·1 per cent.).

Sickness and mortality from pneumonia declined, and there was no virulent outbreak in the Sind Gang, improvements in which, it is hoped, will render the disease no longer formidable. There was a marked decline in malarial fever. There were only 16 cases of plague and 10 deaths.

Andamans.

In 1905 the rainfall in the Andamans was below normal. The provision of permanent barracks has not kept pace with the steady increase in the convict population, but many bamboo and thatch barracks were constructed and occupied, while additional wards were provided for lunatics and for phthisical and other hospital patients. No change has been made in the water-supply and conservancy arrangements. An improvement has been effected in the diet and in the milk supply. In 1905 the average daily strength was 14,348, the admission-rate 1,898, the constantly-sick-rate 68, and the death-rate 38·96 per 1,000. The sick-rate and death-rate were higher than in 1904 owing to dysentery and cellulitis. Malarial fevers, the great scourge of the Settlement, accounted for 65 per cent. of the total admissions to hospital, dysentery and diarrhœa for over 11 per cent. Of the total mortality, 31 per cent. was due to respiratory diseases, including phthisis, and 35 per cent. to dysentery and diarrhœa. The lower admission and death-rates from tubercle of the lungs are ascribed to the vigorous measures adopted against the disease.

V.—VACCINATION.

General results.

Vaccinations are chiefly performed by a special department, which in 1905-6 comprised 15 European and 488 native supervising officers and 6,777 vaccinators, but a small proportion is performed by the staff at hospitals and dispensaries. During 1905-6 9,277,896 persons were vaccinated in India, being an increase of 333,147 on 1904-5. The increase was spread over all the provinces except Madras and Bombay, the rise being notable in Bengal. The number of primary operations was 8,586,770, and the percentage of success 97·20. According to age, 4,161,967 children under one year of age, and 3,474,929 children between one and six years were successfully vaccinated. The proportion of the population protected against small-pox by the year's operations ranged from 55·45 per 1,000 in Coorg to 27·35 in Bombay Presidency, the mean proportion of the total population successfully vaccinated being 36·39 per 1,000 as against 34·79 in 1904-5. The cost of the special department was £85,510.

The following statement shows the results of vaccinations in 1905-6:—

Province.	Population among whom Vaccination was carried on.	Number of Persons vaccinated (including re-vaccinations) by special department and dispensary staff.	Ratio of successful Vaccinations per 1,000 of Population.	Number of Children successfully vaccinated.		Percentage of Annual estimated Births at 40 per 1,000 of Population successfully vaccinated.
				Under One Year of Age.	Between One and Six Years of Age.	
Bengal	51,656,383	2,041,230	37·94	809,606	973,461	39·18
Eastern Bengal and Assam ...	30,788,134	1,429,026	44·86	414,109	804,891	33·62

TOTAL	237,395,617	9,277,896	36·39	4,161,967	3,474,929	43·83

Bengal.

Vaccination in the reconstituted province of Bengal continues to make good progress. The results of vaccination work during 1905-6 show a rise in the proportion of successful vaccinations to 37·94 per 1,000. The increased work is mainly ascribed to more careful supervision, rewards to vaccinators, less prevalence of plague, and greater prevalence of small-pox. A severe outbreak of small-pox increased the number of re-vaccinations by over 50,000 in Calcutta. Much improvement is expected from the new scheme for the better training of vaccinators and inspectors, and from the wider use of prepared lymph. Out of the 33 districts there was an increase of vaccinations in 23 and a decrease in 10. Of the total primary vaccinations 151,080 were performed with calf lymph, 400,847 with lanoline lymph, and 1,352,698 by the arm to arm process, the ratio per cent. of success under each of these methods being 98·92, 96·57, and 99·21 respectively. Infant vaccination is making progress, especially in Calcutta.

Owing to efforts made to cope with the small-pox outbreak the Calcutta vaccination returns showed a large increase, the total number of persons vaccinated (85,287) being 57,235 more than the number in the previous year. The Department has been remodelled. An Animal Vaccine Depôt has been established.

Eastern Bengal and Assam.

There was an increase of vaccination work in this reconstituted province, especially in the Chittagong, Faridpur, and Noakhali districts. The percentage of successful primary operations was 98·28. Re-vaccinations were relatively few. Vaccination of children under one year of age increased, 33·62 per cent. of the estimated number available being protected. The quality of the lymph produced at the Animal Vaccine Depôt at Shillong was uniformly excellent. The use of human lymph is gradually ceasing, though in 1905-6 51 per cent. of the operations were from arm to arm, while 29 per cent. were from manufactured vaccine.

United Provinces of Agra and Oudh.

In spite of the great prevalence of plague and cholera in this province during 1905-6 the number of vaccinations increased by 23,656. There was an increase in primary vaccinations, and a decline in re-vaccinations. The percentage of successful primary cases in which the results were known was a little higher than last year, viz., 97·93 against 97·62. Of the estimated number of children 49·57 were successfully vaccinated. Bovine lymph depôts were maintained at Lucknow and Patwa Dangar (Naini Tal). The latter is a new depôt, well equipped, and its utility has already been amply proved.

Punjab.

Though seriously interfered with by plague, the number of vaccinations in the Punjab increased by 28,968 cases, or 4 per cent. There is strong prejudice, especially in the case of females, against re-vaccinations, in which, however, the percentage of success increased to 83·78, though the number of operations was smaller by 27,323. Of the estimated number of infants under one year of age, 62·54 per cent. were vaccinated. Chloroformed glycerinated lymph of good quality is now prepared at the Central Vaccine Institute, Lahore. Of 100,768 primary vaccinations performed with it in 1905-6, no fewer than 99·94 per cent. were successful.

North-West Frontier Province.

In the North-West Frontier Province the total number of operations rose by 23,824. Of these 87,771 were primary cases with a percentage of success of 98·56. Calf lymph from the Lahore Depôt was used in the great majority of operations. Out of the ten municipal towns in the province, the Vaccination Act is now in force in all but two, viz., Peshawar and Takki. Though the local administration recognises the advisability of extending the Act to other towns, and especially to Peshawar, it is considered that the initiative should be taken by the local bodies.

Burma.

The total number of vaccinations performed in Burma rose in 1905-6 by 75,924. The increase was especially large in re-vaccinations, which also showed improved results. The increase in vaccination was notably great in Rangoon. In primary vaccinations the percentage of success rose from 84·67 to 90·80. Vaccination is wholly with bovine lymph. The whole supply for Burma (excepting Rangoon, where there is a municipal depôt) comes from the central depôt at Meiktila, where useful experiments for improving the preparation of vaccine were carried out. There is a reluctance to allow children under one year to be vaccinated. The newly-sanctioned vaccination staff is to undergo training at the Meiktila Depôt.

Central Provinces and Berar.

There was an increase in primary vaccinations and especially in re-vaccinations during 1905-6. The percentage of success in primary operations was 97·26 and in re-vaccinations 62·83. In recent years plague has hindered vaccination work, but progress has been steady. Of the estimated infant population, 76·75 per cent. were successfully vaccinated. Glycerinated calf lymph is taking the place of fresh calf lymph and human vaccine lymph, and four-fifths of all operations were performed with it, the percentage of success being 93·14.

Madras.

The total number of vaccinations performed in the Madras Presidency during 1905-6 showed a decrease of 49,244 in primary operations, and an increase of 30,965 (or 40 per cent.) in re-vaccinations, as compared with 1904-5. The decrease is ascribed to the short supply of vaccine paste and absence of vaccinators. The shortage in the supply of vaccine paste was due to the bad season in Chingleput, and the poor state of nutrition of the calves. The percentage of success in primary operations rose to 92·67, against 87·38 in 1904-5. A satisfactory feature of the year's work is an increase in the number of children under one year of age successfully vaccinated, but the total number represented only 30 per cent. of the estimated number available. An inspector visited the more backward districts to train vaccinators in the use of the paste. Lanoline lymph, manufactured at the King Institute, Madras, was generally used, and the results showed a marked improvement over those for 1904-5, the success rate being 92·3 per cent.

Bombay.

The steady increase in vaccination work in recent years was not continued in 1905-6, a fall occurring in the re-vaccinations. Out of the total primary vaccinations 97·56 per cent. were successful. During the year 52·32 per cent. of the available infants were successfully vaccinated. After trials at the Vaccine Depôt for the preparation of preserved lymph at Belgaum it has been decided to adopt chloroformed glycerine lymph, the use of which is being extended. In re-vaccination the percentages were 80·28 males and 19·72 females, the small proportion of the latter illustrating the difficulties in this class of work.

VI.—MEDICAL INSTITUTIONS.

Civil Hospitals and Dispensaries.

Institutions and Patients.—The institutions included under this head are those classed as (1) State-Public; (2) Local Fund; and (3) Private Aided. The great bulk of their income is derived from Government, local, and municipal funds, and their total expenditure in 1905 was £607,430. The dispensaries not included comprise (1) State-Special (Police, Forests and Surveys, Canals, &c.); (2) Private Non-aided; and (3) Railway, which together numbered 1,446 and provided treatment for about 128,600 indoor and 6,107,000 outdoor patients.

The principal diseases treated in 1905 were malarial fevers, dyspepsia and other disorders of the digestive system, ulcers and other skin complaints, diseases of the eye and ear, diseases of the respiratory system, and worms. The surgical operations numbered over a million.

The following comparative statement shows the number of hospitals and dispensaries under official control in the several provinces of India during 1905 and the previous year, and the number of patients under treatment:—

Provinces, &c.		Number of Institutions.	Number of In-door Patients treated.	Number of Out-door Patients treated.	Total Number of Patients.
Bengal	1905	305*	33,384	2,328,545	2,361,929
	1904	494	44,228	3,965,347	4,009,575
Calcutta and Howrah	1905	15	25,168	263,267	288,435
	1904	15	24,370	263,020	287,390
Eastern Bengal and Assam	1905	331*	21,714	2,881,907	2,903,621
	1904	120	6,794	946,895	953,689
United Provinces of Agra and Oudh	1905	343	52,432	3,633,557	3,685,989
	1904	344	50,855	3,584,200	3,635,155
Punjab	1905	264	57,091	3,199,250	3,256,341
	1904	257	55,017	3,250,607	3,305,624
North-West Frontier Province ...	1905	37	8,129	528,061	536,190
	1904	36	8,321	569,614	577,935
Burma	1905	141	55,610	967,245	1,022,855
	1904	140	50,593	972,790	1,023,383
Central Provinces and Berar	1905	149	12,497	1,611,525	1,624,022
	1904	150	12,147	1,550,889	1,563,036
Coorg	1905	7	1,005	43,189	44,194
	1904	5	792	41,849	42,641
Madras	1905	491	66,930	5,170,575	5,237,505
	1904	493	60,449	5,150,892	5,211,341
Bombay	1905	301	51,068	2,125,324	2,176,392
	1904	296	48,141	2,085,863	2,134,004
TOTAL	1905	2,384	385,028	22,752,445	23,137,473
	1904	2,350	361,707	22,382,066	22,743,773

* Provinces reconstituted.

Bengal.

Owing to the reconstitution of the province the figures for 1905 and 1904 are not comparable. In the area now included under Bengal there was an increase in the number of patients, ascribed partly to the unhealthiness of the year, partly to the increased confidence of the people in the medical charities, which, in the last few years, have much improved in general management and efficiency. A satisfactory feature in the returns is the increased popularity of the dispensaries among female patients and children. The patients suffering from malarial fever numbered 24·5 per cent. of the total. Cholera and plague were much more prevalent than in 1904. The death-rate amongst the in-patients was 10·8 per cent. The number of operations performed was 152,227. Among the more important operations there were 2,239 cases of cataract. In several districts the work of the dispensaries has been supplemented by measures for supplying medical relief to outlying markets.

Calcutta and Howrah.

Much is still being done to modernise the chief general hospitals in Calcutta. In 1905 at the 15 institutions there was an increase in the number of indoor patients, ascribed to the unhealthiness of the year, small-pox, cholera, plague, and diarrhœa being prevalent. The number of women and children is increasing. The total number of operations performed during the year was 30,110, against 30,353 in 1904.

Eastern Bengal and Assam.

Owing to the reconstitution of the province the figures for 1904 and 1905 are not comparable. The number of in-patients was 21,714, and of these 2,001 died, giving a death-rate of 9·2 per cent. against 8·1 in 1904. Of the various diseases for which the patients were treated the largest numbers were skin diseases, worms, and malarial fevers. Cholera and small-pox cases greatly increased. The total number of operations was 73,989, of which 113 were fatal. Of the operations, comparatively few were important.

United Provinces of Agra and Oudh.

The hospitals maintained their popularity. The year was a heavy one, owing to epidemics of plague and cholera, and the strain on the medical staff was severe. Several hospitals have been improved. Special attention has been paid to the surgical equipment and to operating rooms. More Hospital Assistants are needed. The Agra Medical School has been enlarged. A medical college is being erected. There was a large increase in the number of patients during 1905. Among the in-patients the death-rate was only 4·54 per cent. There was a great decrease in cases of malarial fevers, but an increase in cases of skin disease and respiratory disease. The number of surgical operations increased to 184,346, including a large number of simple operations for evacuation of abscesses and teeth extractions, and of these 161,713 resulted in cure, while 428 were fatal. The number of visits to patients in their homes by Lady Doctors and Hospital Assistants was 4,676.

Punjab.

There were 264 hospitals and dispensaries at work in the Punjab at the close of 1905. The attendance of in-patients exhibits an increase on that of the previous year. A satisfactory feature was the larger number of women and children. Of the 57,091 in-patients, 3·17 per cent. died, against a mortality of 3·42 in 1904, a satisfactory decline. The healthiness of the year, apart from plague, diminished the number of out-patients. The severe plague epidemic did not affect the popularity of the indoor dispensaries. There was a decline in malarial fever, spleen, and eye cases, and a marked rise in diseases of the skin and respiratory system. In the number of surgical operations performed (180,408), there was an increase of 7,965, and the total was the largest on record. Of the total operations only 0·15 per cent. were fatal. The percentage of deaths has declined. There were 7,683 operations for cataract, and of these 6,403 were successful.

North-West Frontier Province.

The slight decrease in the number of patients treated appears to have been due not to any decline in the popularity of the dispensaries in the North-West Frontier Province, but to the healthier conditions prevailing during the year 1905. Of the 8,129 in-patients, 6,000 were cured and 281 died. The chief diseases treated were malarial fever, diseases of the eye, and ulcers. There was a large increase in patients suffering from tubercular and respiratory diseases. The total number of operations performed was 23,982, a small increase on 1904.

Burma.

Of the in-patients 6 per cent. died, as compared with a mortality of 5 per cent. in the previous year. As usual malarial fevers headed the list of diseases for which patients sought treatment, next in order being worms, ulcers, diseases of the eye, skin diseases, and diseases of the digestive system. There were more admissions for cholera and small-pox. The number of surgical operations continued to increase, and in 1905 aggregated 24,536. Amongst the patients operated on only 0·36 per cent. died. Important operations were few. The attendance of women and children at hospitals in Burma is comparatively small, but the provision of better arrangements for women is being attended to. Medical work in Burma is hampered by the difficulty of recruiting suitable men as Assistant Surgeons and Hospital Assistants. The equipment and appliances of the institutions are being improved.

Central Provinces and Berar.

During the year 1905 there were 149 hospitals and dispensaries at work in the Central Provinces and Berar, and 1,624,022 patients were under treatment. Both in- and out-patients increased, and but for plague, this increase might have been greater. The number of in-patients was 12,497, of whom 6·4 per cent. died. As regards the different diseases, ulcers and other skin diseases, malarial fever, diseases of the digestive system, diseases of the eye, and respiratory diseases were most numerous. The surgical operations performed during the year numbered 40,942. The female attendance has slightly increased, but is smaller than might be expected.

Madras.

In the hospitals and dispensaries of the Madras Presidency more patients are treated than in those of any other province. About 15 per cent. of the total population were attended to in 1905. Of the 66,930 in-patients, who largely increased,

6·75 per cent. died, against a death-rate of 5·9 per cent. in 1904. Among the diseases treated the most important were ulcers and other skin diseases, diseases of the digestive system, malarial fevers (which showed a large decline), worms, diseases of the eye and ear, respiratory diseases, and rheumatic affections. There were increases in dysentery, diarrhœa, and tubercular diseases. During the year 187,436 operations were performed. The results show that only 0·25 per cent. died. The surgical equipment and operation rooms have been improved. The popularity of medical institutions appears to be growing.

Bombay.

The in-patients numbered 51,068, and of these 32,386 were cured and 5,915, or 11·6 per cent. died. Among patients the most common diseases were, as usual, malarial fever, diseases of the skin and the eye, worms, and respiratory affections. The surgical operations performed during the year numbered 82,113. In all the large hospitals in Bombay City, and in some of those in the mofussil, buildings, furniture, fixtures, and instruments have been improved. The employment of trained nurses is being slowly extended.

Lunatic Asylums.

The following table shows the strength of the asylum population in 1905 and the statistics of sickness and mortality:—

Administrations.	Admitted and Re-admitted during year.	Total Asylum Population.			Discharged Cured.	Died.	Daily Average Strength.	Daily Average Sick.	No. of Criminal Lunatics.
		Male.	Female.	Total.					
Bengal	219	857	203	1,060	83	77	837	70	513
Eastern Bengal and Assam...	105	439	91	530	50	32	429	31	264
United Provinces of Agra and Oudh.	503	1,296	390	1,686	131	105	1,199	93	450
Punjab	184	612	148	760	70	56	597	42	142
Burma	150	522	73	595	36	33	454	32	269
Central Provinces	68	268	90	358	34	29	293	8	91
Madras	185	584	187	771	65	86	587	63	164
Bombay	367	951	252	1,203	125	52	868	22	162
Total, 1905 ...	1,781	5,529	1,434	6,963	594	470	5,264	361	2,055

The total number admitted into asylums in 1905 was 1,667, the average for the five years to 1905 being 1,401. The total asylum population of the year was 6,963. The lunatics in asylums represent only a small proportion of the insane population.

Owing to the difficulty of ascertaining the history of patients the causes of insanity are in most cases unknown. The commonest forms of insanity are mania and melancholia.

Bengal.

The Berhampur asylum has been enlarged and the Dullunda asylum closed. The Cuttack asylum is also to be closed. A new central asylum is to be erected at Ranchi, and placed under an expert alienist. The figures for 1905 in the above table for Bengal relate to four asylums, viz., Bhowanipur, for Europeans, and Cuttack, Patna, and Berhampur, for natives. There has been an increase in the asylum population in recent years. Mania and melancholia are the chief causes of admission. In a large percentage of cases the causes of insanity are not ascertained. The death-rate is not high. Improvements in the management has taken place in the direction of the "non-restraint" system.

Eastern Bengal and Assam.

In the reconstituted province of Eastern Bengal and Assam these are two asylums (Dacca and Tezpur). Both were reported overcrowded, especially Tezpur. The death-rate was high at the Dacca asylum, mainly owing to tubercle of the lung, but the rate for the two asylums was not above the general average for India.

United Provinces of Agra and Oudh.

There are four lunatic asylums (Agra, Bareilly, Benares, and Lucknow) in the United Provinces of Agra and Oudh. The general health of the patients was good, except at Benares, where the health of the city was unsatisfactory. The death-rate was low. Mania was the chief cause of admissions, followed by dementia and melancholia.

Punjab. The population of the asylum at Lahore increased. Owing to the increase of patients the asylum has become overcrowded, and enlarged accommodation is being provided. A special building has been opened for females, and a new and better system of nursing introduced for women patients. Insanity is less common among women than among men, but the percentage of recovery is lower among women.

Burma. The Rangoon Asylum, which is the only one in Burma, has accommodation for 427 insanes. There was considerable overcrowding, but plans and estimates are under discussion for the erection of a new and larger asylum near Mandalay. The health of the asylum was unsatisfactory during the year, but the death-rate showed a marked improvement. The staff has been increased and various sanitary improvements have been effected.

Central Provinces. There are two asylums in the Central Provinces (Nagpur and Jubbulpur). There is overcrowding at Jubbulpur. It is proposed to remove all female lunatics to Nagpur. The general health of the asylum population improved with a substitution of wheat for millet as the staple diet at Nagpur, but the mortality-rate has remained high.

Madras. In the three asylums (Madras, Vizagapatam, and Calicut) of this Presidency the accommodation was ample, and there was no overcrowding in any of them during the year. There was more sickness among the patients than in 1905, especially from cholera and diarrhœa, and the death-rate was also higher.

Bombay. There are at present seven asylums in the Bombay Presidency. A new central asylum is to be erected at Yeravda, near Poona. The health of the inmates was on the whole satisfactory. Mania and melancholia are the chief causes of admission, but the history of many cases is unknown. Soldiers furnish the largest number of admissions. The death-rate tends to decline.

Medical Schools.

Bengal. The Medical College, Calcutta, and three of the medical schools are maintained by Government, the rest are unaided. The Government medical schools train pupils as Civil Hospital Assistants, and the unaided schools follow their own standards for private practice.

The total strength of the College at the end of the session 1905-6 was 443 (including 17 women). In the Preliminary Scientific M.B. examination 33 out of 68 candidates passed; while five out of seven passed the first and six out of 18 the second M.B. examinations. In the combined Preliminary Scientific and First L.M.S. examinations there were only five candidates, of whom three passed; and 26 out of 30 passed the combined Scientific and First M.B. examinations.

The average number of students attending the Government Medical Schools was 461.

Eastern Bengal and Assam. The Dacca Medical School had 166 students as against 179 in 1904-5, while the Berry-White Medical School at Dibrugarh had 125 as against 96. At the Second Licence Examination there were 38 successful students from the former and 18 from the latter.

United Provinces of Agra and Oudh. The number of pupils attending the Agra Medical School in 1905-6 was 317 (including 75 women), or 20 more than in the preceding year. The results of the final examinations of the men were excellent. Of the 15 female candidates only seven were successful, but one of them, Ram Pyari, gained all the three medals and the prize offered to women. A hostel to accommodate 168 students was opened in October, 1905. The dissecting-room is being enlarged, and a new lecture theatre and class-room have been provided.

Punjab. Lack of material for anatomical purposes has necessitated a restriction of the numbers admitted into the Medical School, while the raising of the literary test for entrance also contributed to the reduction. The average attendance at the Lahore Medical College and School fell from 599 to 552. Of these 260 were in the College and 292 in the Medical School. The percentage of passes in the examinations for the medical degree were not high, but those for the hospital assistant diploma yielded excellent results. The results of the year's examinations show that for the Preliminary Scientific Examination 41 out of 89 candidates passed. In the first L.M.S. and M.B. examinations 26 candidates out of 76 passed, and in the second

L.M.S. and M.B. examinations 19 out of 28 passed. In the School department 102 candidates went up for the final examination for the hospital assistant diploma and 80 passed, or 78 per cent.

The North India Medical School for Christian women at Ludhiana had 38 students on the rolls at the end of 1905, or five less than in the previous year; of these 15 belonged to the Medical Assistants' class, five to the Compounders' class, 12 were being trained as nurses and the rest as *dais*.

Madras.

The strength of the Madras Medical College during 1905-6 was 189. At the final L.M. and S. and M.B. and C.M. examinations the College passed 33 and 46 per cent. of the candidates sent up. In the School department the students numbered 149 (including 20 women) and for the final examination for the Apothecary grade 19 candidates appeared, 17 of whom passed.

The medical schools at Rayapuram, Vizagapatam and Tanjore combined had on their rolls 262 pupils, and of these 51 appeared at the final examination of hospital assistants and 39 passed. All these schools are now under Government management.

Bombay.

The attendance at the Grant Medical College, Bombay, rose from 694 in 1904-5 to 697 (including 40 women) in 1905-6. For the first L.M.S. examination 181 candidates presented themselves, of whom 95 passed; and for the second L.M.S. examination 101 passed out of 187 candidates. For the final examination for the degree of L.M.S. there were 172 candidates, and of these 50 passed, two of whom were women.

The Government Medical Schools at Poona, Ahmedabad, and Hyderabad (Sind) continued to work satisfactorily. The combined average daily attendance was 287.

Central Research Institute, Kasauli.

This Institute has been fully equipped with apparatus requisite for six to eight workers. The duty of preparing sera has been transferred to it from the Pasteur Institute. In March, 1906, the staff of the Institute began an investigation in connexion with the etiology and spread of enteric fever in India. Two officers have received a two months' course of instruction in technique, qualifying them for investigations connected with malaria, *kala-azar*, and blood diseases generally. In March, 1906, the staff of the Institute began an investigation of the etiology and spread of enteric fever in India.

King Institute of Preventive Medicine, Guindy, Madras.

The institute is divided into two sections, the vaccine and the bacteriological. It serves as a training centre for sanitary assistants, vaccinators, and plague inspectors, and the laboratories, which are well equipped, are available for the instruction of officers and for research work. The Vaccine Section supplied lanoline vaccine paste sufficient for 1,633,250 cases. The difficulties of production caused a shortage of supply in the summer months. The laboratories of the Bacteriological Section were increasingly utilised, especially in connexion with plague specimens. Samples of water, &c., were examined in connexion with public health work. Several medical officers used the laboratories for research or instruction. Lectures were given in sanitary engineering, vaccination, and bacteriology.

Pasteur Institutes.

The steady increase in the number of patients treated at the Kasauli Institute continued during 1905-06, and 1,145 people were treated for bites from rabid animals, including 342 Europeans. Patients came from every province and from outside areas, while 172 patients were from the British Army and 82 from the Native Army. In addition to the anti-rabic treatment the Institute undertook the preparation of anti-diphtheritic serum and of anti-venene. A considerable amount of research work was carried out, and bacteriological examinations, serum diagnosis, &c., were conducted. A Pasteur Institute for Southern India is being established at Coonoor.

VII.—SANITATION.

Bengal. In the reconstituted province of Bengal there was an increase of expenditure on conservancy and drainage by municipalities in 1905 as compared with 1904, but a smaller outlay on water-supply than in 1904, when it was exceptionally high. There is considerable activity in municipal sanitation, especially in regard to latrines and schemes for surface drainage. Attention has been directed to the biological method of sewage disposal.

A capital outlay of £67,000 is being incurred by Howrah in carrying out drainage schemes. Plans for the improvement of drainage were also in progress in Titaghar, Cossipore-Chitpur, Puri, and several other municipalities. In the towns of Monghyr, Khulna, and Barisal schemes for extending or improving the water-supply were in preparation. The sanitary work performed by district boards included preventive measures against cholera, plague, &c., sanitary arrangements at fairs, and improvements in village sanitation by clearance of jungle, excavation of roadside drains, and the filling up of hollows containing stagnant water.

The Sanitary Board held only two meetings during the year, and continued to advise the Government and local bodies on important projects relating to waterworks and drainage. The Board proposed modifications in the rules for the preparation of drainage and water-supply schemes. An Assistant Engineer is to be appointed to supervise such schemes.

Calcutta. Progress has been made with the suburban drainage scheme, but the difficulties connected with the syphon under Tolly's Nullah remain unsettled. The greater part of the estimated amount of £97,000 for improving the filtered water-supply has been expended, and a further outlay of £8,500 for two new filter beds at Pulta has been sanctioned. Better maintenance of the pumping engines, and the laying of new and larger mains, are among the improvements effected. The conservancy arrangements have been improved during the year. A final decision has not yet been reached regarding the initiation of the great city improvement scheme.

Eastern Bengal and Assam. In the reconstituted province there are 44 municipalities. The conservancy system in Dacca is unsatisfactory, and schemes for drainage and other sanitary improvements are being considered. Proposals for waterworks are under discussion at Chittagong, and in other towns. The Gauhati waterworks were entirely remodelled in 1905. Most of the districts report improvements in the water-supply of the larger villages by excavating and cleansing tanks and digging wells.

A Sanitary Board was formed but no meeting was held during the year.

United Provinces of Agra and Oudh. In the United Provinces of Agra and Oudh many sanitary improvements in various directions were effected during the year 1905. Good progress was made with the drainage works at Benares, Cawnpore, Agra, Mirzapur and Lucknow, and many other drainage schemes are projected or in progress. The waterworks at Agra, Allahabad, Benares, Cawnpore, Lucknow and Meerut gave excellent results, and extensions were in progress. The Government have relieved the municipalities of police charges to the extent of over £23,000, and this sum is being expended chiefly on plague measures and sanitation. Experiments were made with regard to new methods of treating domestic sewage.

The Sanitary Board held four meetings during the year at which they considered and approved projects, amounting to over £125,700, for improving the sanitary condition of municipalities. The Sanitary Engineer's report on the quality of the several municipal water-supplies was very satisfactory. The Board approved a large number of schemes for drainage and sewerage works. The appointment of an Assistant Sanitary Engineer has been recommended.

Punjab. Progress was made with various drainage and water-supply schemes in the Punjab. Measures are being taken at Lahore and Simla to check the waste of water. There was a marked increase in the number of municipalities that dispose of sullage to cultivators for sewage irrigation. The drainage schemes for Delhi, Multan, Rawal Pindi, Amritsar, and Umballa have been put in operation and good progress made. An estimate of £26,700 for waterworks at Ludhiana was sanctioned. Continued attention was given to village sanitation, and progress

was made in the clearance and protection of wells. Several works of public utility that serve sanitary purposes, such as wells and rest-houses, were constructed by private individuals at their own expense.

Five meetings of the Sanitary Board were held during the year, when several drainage and water-supply schemes were considered and approved and forwarded to the Local Government for disposal.

North West Frontier Province.

No important sanitary work was carried out in the North-West Frontier Province in 1905, but considerable sums were expended on minor works for water-supply and drainage in the municipal towns, especially in Peshawar, the sanitary state of which is very creditable. Progress was made with drainage schemes in Kohat.

Burma.

The municipalities of Burma spent 45 per cent. of their income on sanitary works. Of the district funds less than 5 per cent. was devoted to sanitary purposes. No progress in village sanitation can be recorded. The villagers are said to be apathetic and heedless of the filth of their surroundings. Improvements in water-supply are especially needed. The Hlawga water-supply scheme at Rangoon, designed to augment the supply from Victoria Lake, was opened in February, 1905, but to ensure an abundant supply increased pumping power and improved means of distribution are required. An estimate for an improved sewerage system at Rangoon has been sanctioned. The Moulmein water project has been completed, while estimates for waterworks for Akyab have been sanctioned. The revised scheme of water-supply for Mandalay is still pending. Schemes for drainage and waterworks in several minor municipalities were in progress.

The Sanitary Board held two meetings. In future there are to be four meetings a year, and the functions of the Board will be purely consultative.

Central Provinces and Berar.

No new sanitary work of importance was undertaken in the Central Provinces and Berar during 1905. There was considerable activity in conservancy and other sanitary matters in many municipal towns, especially in Nagpur. Nagpur, Seoni, and Bhandara spent considerable sums in improving their water supplies. A comprehensive drainage scheme for Nagpur was under consideration. Drainage schemes for Khandwa and Burhanpur are also contemplated. In the villages expenditure was incurred for improvement of village sites and surroundings, the construction of new wells and repair of old ones.

Meetings of the Sanitary Board were held during the year in every district. A record of desirable works of village sanitary improvement has been prepared in some districts. A special grant of £4,759 for improving village water-supplies, &c., was expended, and it is hoped that a water-supply will be provided in all localities in need of it.

Madras.

Estimates for many water-supply and drainage schemes were submitted in Madras Presidency. The Coonoor, Guntur, and Dindigul waterworks were completed, and similar works were commenced at Vellore, while schemes for Salem and Coimbatore were examined. A drainage scheme for Madura town was under discussion. Many towns still lack proper water-supply and drainage, and some suffer seriously from congestion and lack of proper sanitation, owing to lack of funds or the slackness of municipal councils. Attention has been drawn to the serious question of congested areas and overcrowded dwellings. Ryots are exhibiting less caste prejudice in the utilisation of night-soil as manure. More energetic stimulation of Local Fund Boards by medical and sanitary officers is said to be desirable. No Board had yet provided a piped public water-supply.

The Sanitary Board scrutinized the plans and estimates relating to 101 sanitary works, estimated to cost £423,870, and 66 were approved.

The important scheme initiated some years ago in Madras of training sanitary inspectors has worked with marked success, and 517 inspectors have been registered as having undergone complete courses approved by Government.

Madras City.

In Madras City good progress was made with the new drainage scheme, which should remedy the most serious sanitary defects, and a number of minor improvements in sanitation, drainage, and water-supply were carried out. Estimates have been prepared for important schemes to improve the water-supply. The cost is estimated at £150,000.

Bombay.

Progress in sanitation in municipal towns has once again been retarded by financial difficulties arising from expenditure on plague. Hence many urgent schemes of

water-supply and drainage could not be carried out. Altogether £26,559 was spent on new works under these heads. With the exception of Ahmedabad no municipality of the Presidency was in a condition to undertake costly works. At Ahmedabad the extension of the drainage has cost £100,000, but a further outlay of a like amount is necessary to complete a sewerage scheme for the whole city. The waterworks of Ahmedabad also require extension and improvement. Arrangements were in progress for the extension of the Karachi drainage, for which a loan of £36,700 has been raised. Estimates for a water-supply scheme for Poona were under discussion, as also a drainage scheme. The Village Sanitation Act was in force in 234 villages against 261 in the previous year. The Act provides for the establishment of a sanitary committee or a sanitary board, consisting of members chosen by the collector of the district or by the local Government to supervise sanitary matters. Sanitary inspection books had been introduced into 3,410 villages, and in 89 per cent. of these the books had been written up by officers of the Sanitary Department. Sanitary officers made suggestions for the improvement of village water supplies, surface drainage and conservancy.

The Sanitary Board considered the question of financial and technical assistance to municipalities to stimulate progress on sanitary works, and submitted recommendations to Government.

Bombay City.

In Bombay City progress was made with the Malabar Hill sewerage scheme. Other sewerage schemes were also undertaken. The lakes and reservoirs which supply the city with water were maintained in good condition. The rainfall, however, was below the average of the quinquennium. In the course of the year 512 new water connections were made and 245 were cut off, leaving a total at the end of the year of 21,188.

INDIA OFFICE,
5th June, 1907.

ABSTRACT OF THE REPORT OF THE SANITARY COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1905.

Meteorology of the Year.

The chief meteorological features of the year 1905 were—

(1) The severity and persistency of the cold weather conditions as shown by the amount of snow and rain in Northern India, and the lowness of the temperature over the greater part of the country. This low temperature lasted until the end of April.

(2) The lateness and scantiness of the monsoon rains, especially in North-West India, and the consequent high temperature.

(3) The extreme weakness of the retreating monsoon in the Peninsula, except in Malabar and the extreme south of the Madras Presidency.

During the first twenty days of January weather was feebly unsettled in Northern India with occasional showers in the plains and snow in the hill districts. Temperature there was accordingly very unsteady, but the departures from the normal were at no time very large or important. In the Peninsula, on the other hand, weather was generally dry, and temperature moderately high during this period. On the 21st a fairly deep depression entered Northern India from the west, and occasioned heavy precipitation in North-West India, and showers in the north-east. It was followed by a very strongly-marked cold wave, which appeared on the north-west frontier on the 21st, and advancing across Northern India during the next five days reached Upper Burma on the 26th. Maximum or day temperatures were from 12° to 32° and the night temperatures from 8° to 26° below the normal during this period, and severe frost was experienced both on the hills and plains, a number of stations registering the lowest night temperatures on record. As usual during the cold season these low temperature conditions did not extend to Madras. A second depression appeared in Baluchistan towards the close of the month, and gave showers in North-West India.

February opened with unusually low temperature over the whole country, except in the extreme south and Burma. These low temperature conditions lasted throughout the month, but were, on the whole, most marked during the first three days, during which period a large number of stations experienced much lower temperatures than any previously on record for February. Sharp frost occurred in many parts of Northern and Central India. On the mean of the whole month temperature was in very large defect in Northern India and the Deccan, the defect ranging from 5° in the Deccan to 9° in the Upper Sub-Himalayas. The day temperature was more affected than the night temperature, and in consequence the daily range was much smaller than usual. Weather, on the other hand, was warmer than usual in Madras.

The cold weather which ordinarily does not outlast the end of February was in the present year prolonged into March and the greater part of April. Five depressions in all affected the weather in March. Two of them were important and gave fairly heavy rain over Upper India and very heavy falls of snow in Kashmir. Practically no rain occurred during the month in Lower Sind, Gujarat, Western Rajputana, Bombay, and the west of the Central Provinces, and of the Deccan, as well as within small areas over the South Madras coast and the coast of Lower Burma.

Temperature in March was as markedly in defect as during the two preceding months; the only exceptions occurred in South Madras, Mysore, and the Tenasserim Coast.

In April conditions were, on the whole, less disturbed than they had been since the beginning of the year. The precipitation of the month exceeded the normal in Bengal, the Central Provinces and Madras, but was normal or in defect in the remainder of the country; the defect was most pronounced in Burma, where the usual thunderstorms were almost entirely absent. The most noteworthy feature of the

meteorology of the month, however, was the abnormally low temperature over nearly the whole of the Indian region. The defect was considerable to large over Northern India, where both day and night temperatures averaged from 4° to 7° below the normal.

In May a considerable change occurred in the conditions that had prevailed so far. Little or no rain fell over the dry area in the north-west, and the precipitation of the month was less than the average in all districts excepting Upper Burma, Bengal, Orissa, Ganjam, the east and centre of the Central Provinces, and parts of the south and south-west of the Peninsula. Accordingly, the low temperatures of the previous four months disappeared, and were replaced by an excess except in North-East India, the Gangetic Plain, and the coast districts of the Peninsula.

June was unusually dry over by far the greater part of the country. The monsoon rains were greatly retarded on both sides of India, not setting in till the 10th on the Bombay Coast, and the 29th in Bengal. The Arabian Sea current was weak and unsteady, and it was not until the 27th that it penetrated into the interior. The rainfall was in excess of the average in Burma, Assam, and the south of India, and in those regions the temperature was in very slight defect. On the other hand, in the remainder of the country where the rainfall was less than the average, the temperature was much above the normal, the excess amounting to 8° in Chota Nagpur.

In July the rainfall of the month was lighter than usual, and the temperature above the normal over a considerable part of the country. At the commencement of the month a fair amount of rain was falling over the Peninsula, the central parts of the country, and North-East India, but very little elsewhere. There was, in consequence, a considerable excess of temperature over Northern India, a slight excess over the Peninsula, and a considerable deficiency over the central parts of the country across the head of the Peninsula. This distribution of temperature continued till the 5th; between the 6th and the 10th the temperature conditions were largely controlled by the rainfall of a depression which passed westward from Bengal through the central parts of the country and disappeared on the 10th. During this period the mean temperature was steadily high over North-West India and over the Peninsula, and low elsewhere—more particularly at the central stations. A great change then occurred. A shallow storm appeared at the head of the Bay on the 11th, and passing through West Bengal, disappeared over the United Provinces on the 15th. A strong flow of monsoon winds into Northern India occurred during this period, occasioning fairly heavy general rain, and bringing about a great reduction of temperature. The greatest deficiency was shown in the day temperature which was from 15° to 27° below the normal at several stations in the Punjab and Kashmir. During this time there was no rain of importance over the Peninsula, and the mean temperature ranged above the normal. As the rainfall grew lighter and contracted in the north this area of excessive temperature spread northward, and on the 16th, 17th, and 18th the mean temperature exceeded the average in nearly all parts of the country, except Burma and North-East India. Between the 19th and 25th another depression passed from the head of the Bay westward, as far as lower Sind, occasioning rain over the central parts of the country and the Peninsula. The rainfall was heaviest over Gujarat, and the greatest depression of temperature was reported from that area. Showers fell over the North-West Himalayas and neighbouring districts on the 23rd, and the mean temperature was lower than usual over the North-West Frontier Province for some days. In other parts of the Indian land area the mean temperature was generally higher than usual between the 20th and the 28th. On the 27th a fresh depression appeared over Bengal and marched northward through that province. Rain fell over Burma and in the north-east, and the mean temperature became lower than usual over these areas.

August was even drier than July, the total rainfall of the month being below normal in all parts of the country with the exception of Assam, Bengal, Bihar, and Madras. The deficiency was greatest in North-West India, which obtained only 20 per cent. of its normal supply. Temperature in consequence was more or less above the normal over the whole of the Peninsula and North-West and Central India; the excess was most marked in Rajputana and the adjacent districts of the Punjab, where it averaged nearly 6° in amount. The heat in the north-west was most intense between the 19th and 21st, when maximum temperatures ranging up to 111° and from 10° to 15° above the normal were recorded at several stations.

During September rain occurred frequently in Burma and North-East India, and the mean temperature there was below the normal; over the remainder of the country, however, rain was infrequent or light, and the heat was greater than usual. The excess of temperature was not so great as in August. The most striking features of the temperature conditions were: (1) a large excess in North-West India during the first ten days of the month; and (2) a large defect over the whole of Northern India from the 11th to 17th. Conditions were very steady over the greater part of the Peninsula, where, on most days, temperature was above the normal.

Weather was less disturbed than usual in October, except in Burma, Assam, parts of Bengal, and the south of the Peninsula, where the retreating monsoon current was somewhat more active than usual. During the first four days of the month the weather was very quiet, and there was little rain beyond light showers in the north-east. In consequence, the mean temperature, except in parts of Assam and Bengal, was generally above the normal, the excess being greatest, and amounting to 5°, over Rajputana and the neighbouring parts of the United Provinces and over the Bombay Deccan and Khandesh. On the 5th rain commenced over the southern half of the Peninsula, and fairly heavy daily rain continued over that region from the 5th to the 21st, when, owing to the formation of a depression over the Bay, and the consequent diversion of the moist current from the south of the Peninsula to the depression area, the fall somewhat abruptly ceased. In consequence of the above rainfall, the mean temperature of the Peninsula was generally lower than usual. During this period temperature over Northern India was unsteady and varied by small amounts from the normal. On the 11th, 12th, and 13th there was some snow and rain over Kashmir and light rain over the Punjab. In consequence a decided fall of temperature took place in the north-west, and in some division the mean daily temperature was reduced to below the normal. On the 14th and 15th it became rapidly hotter in Sind, and these high temperatures spread eastward over Gujarat, Rajputana, and Central India. On the 21st a large shallow low-pressure area lay over the Bay of Bengal, and rain was falling over Burma, deltaic Bengal, Orissa, and the Circars; the low-pressure area gradually concentrated, and on the 23rd a depression was shown off the coast near Vizagapatam. This depression advanced north-north-eastward and north-eastward up the coast, entered Bengal on the 25th, and then passed eastward through Upper Burma and Cachar during the 26th. The storm occasioned a considerable fall of rain in the north-east, and the temperature over Burma, Assam, and Bengal was somewhat lower than usual. During this period the mean temperature was very excessive in the north-west. From the 27th to the end of the month the weather was practically rainless throughout the country, and the mean temperature was generally above the normal, more especially in the north-west, where the average excess ranged between 2° and 10°.

Quiet weather prevailed over the Indian land area during November. From the 1st to the 9th the only rainfall reported was some scattered showers, mainly over Burma, Assam, and the extreme south of the Peninsula. During this period the most marked feature of the weather was the excessive heat prevailing over North-West India, where the mean temperature varied between 4° and 10° above the normal. Temperature was also higher than usual, though to a less extent than in the north-west, over North-East India, the showers in that area having been less frequent and less heavy than usual. On the 10th moderate to heavy rain set in over the southern half of Madras. The rainfall diminished both in amount and extent between the 12th and the 16th, extended again on the 17th and 18th, was light between the 19th and 23rd, but became heavier and more general on the 24th, and subsequently extended along the West Coast reaching as far north as Bombay, Poona, and Ahmednagar on the 27th and 28th. During the period from the 11th to the 15th the temperature was unsteady over Northern India, but was very high over North-West and Central India. On the 16th a fall took place, but, though the mean temperature in the north-west was lowered, the fall was not sufficiently large to bring it below the normal in that area. In the north, east, and centre, on the contrary, the mean temperature fell to below the normal, and remained normal or below till the 24th. On the 25th a decided increase of temperature occurred over the Peninsula, and though the rainfall over the south of the Peninsula, the West Coast, and the Bombay Deccan temporarily made the air cooler than usual in those regions, the interior of the Peninsula remained warmer than the average until the close of the month. In North-West India the temperature remained high during this interval, while in North-East India it was generally normal or below the normal.

Quiet weather prevailed over the Indian region during the first week of December, and the only rainfall reported was a few showers over the south of the Peninsula. The mean temperature was at the commencement of the week generally higher than usual, except over the north-west and the north-east, but temperature gradually fell, and on the 6th, 7th, and 8th was below the average, except in Burma. The deficiency of temperature was especially marked over the centre of the country. On the 8th a barometric depression, which had apparently advanced in a northerly or north-easterly direction from the south of the Bay, was shown over the east of the Bay off the west of the Andamans. It advanced in a north-easterly direction during the next two days, and apparently broke up near the Arakan Coast. It occasioned rainy, unsettled, weather over the Andamans and Burma between the 6th and the 10th, and brought about a considerable fall of temperature in the Andamans on the 6th and 7th, and in Burma between the 8th and 10th. Between the 8th and the 11th temperatures lower than usual prevailed over the greater part of the Indian area, but on the 12th a rise set in, and by the 14th the mean temperature generally exceeded the normal, except over the central districts and along the West Coast. Light showers of snow occurred on the North-West Himalayas between the 13th and 15th, and temperature was unsteady in the extreme north-west, but on the 16th, 17th, and 18th a rise took place, and on the 18th, immediately before the appearance of the second storm of the month, the mean temperature was very high over the whole of North-West India. On the 19th a shallow depression was shown over the Punjab and neighbouring regions, and moderately heavy rain was falling over the North-West Frontier Province and the Punjab. A slight cold wave succeeded this precipitation, and passed slowly across Northern India between the 20th and the 25th. It was succeeded by very high temperatures in the north-west, which, in their turn, extended eastward over the central parts of the country. On the 29th, 30th, and 31st light showers fell in the north-west and north-east, and temperature was reduced to below the normal in both areas; but over the remainder of India the mean temperature was generally in excess of the normal during this period, and in parts of the Deccan, the Central Districts, and Bengal the excess was considerable.

The mean temperature of the whole Indian land area for the year was only 0·4° in defect; the defect was shown entirely in extra-tropical India, temperature being 0·1° in excess in tropical India. It was above the normal in all months of the year with the exception of the first four and December. The defect was unimportant in December, but equalled 4·7° in February and 3·0° in March and April. The excess, on the other hand, was greatest in June, the month of greatest deficiency of rainfall.

The mean pressure of the year was ·009 inch higher than usual. The excess was much more marked in the Peninsula than in Northern India, averaging ·014 inch for the former and ·003 inch for the latter area. The most striking feature of the pressure conditions during the year was the large excess in April and November, associated in the former month with a considerable depression, and in the latter with a moderate elevation of temperature.

The year was drier than usual. The mean relative humidity of the air was slightly below the normal. This dryness was solely a result of a large deficiency of aqueous vapour, the pressure of which was ·012 inch below the normal.

The mean cloud amount was above the normal from January to March, and below it during the remainder of the year. The cloudiest month relative to the normal was March (+ 1·2), and the skies were least overcast in June, when the mean cloud amount was 1·1 below the normal.

The rainfall of the year exceeded the normal over Burma, Assam, Bengal, Bihar, the east submontane districts of the United Provinces, the Central and West Punjab, the North-West Frontier Province, the west of the Central Provinces and Baluchistan, but was lighter than usual in all other parts of the country. The deficiency was largest in Rajputana, Sind, the South-East Punjab, and the Western and Central Districts of the United Provinces, where it ranged between 48 and 62 per cent. The greatest excess, on the other hand, occurred in North Bihar, Central, and Deltaic Bengal and Baluchistan, which received 23 to 32 per cent. more than their normal amounts.

The deficiency of rainfall was not distributed over the whole year, but occurred almost solely in the period June to September.

European Troops.

(For Statistical Tables, *see* pages 127 to 133.)

Sickness and mortality in 1905.—The average strength of the European Army of India during 1905, excluding officers, was 71,343 as compared with 71,083 during 1904, the number of new arrivals in the country during the corresponding trooping seasons having been 15,178 and 16,366 respectively. From the following table it will be seen that the health of the British troops during the year has been exception-

India.	All Causes. Ratios per 1,000.		
	1899–1903.	1904.	1905.
Admissions	1100·6	900·4	834·3
Constantly sick	68·05	57·0	52·3
Deaths	13·46	10·83	10·05
Invalids	33·99	35·27	21·24

ally good, the rates of admission into hospital, of constantly sick, of mortality, and of invaliding all being the lowest on record; and this is the more satisfactory as 52 per cent. of the strength were under 25 years of age, and 25 per cent. had less than one year's service in India. Taking India as a whole, the healthiest months were March, April, May, and June, and the most unhealthy August, September, and January.

The chief causes of sickness were venereal diseases, ague, and simple continued fever, which accounted for 18·42, 13·35, and 5·74 per cent., respectively, of the total number of admissions from all causes. The decrease in sickness was due chiefly to the diminution in the number of admissions on account of ague and venereal diseases. The admission rate for ague was 111·4 per mille against 174·0 in 1904, and an average of 311·2 in the preceding decennium; that for venereal diseases was 153·7 against 198·5 in 1904, and 385·5 for the decennium. Enteric and remittent fevers also show diminished admission rates in comparison with those of 1904 and of the decennium, but the rates for simple continued fever, influenza, and small-pox rose from 23·7, 4·9, and ·7 per mille, respectively in 1904 to 47·9, 14·2, and 1·4, respectively, in the year under review. How far the diminution in the admission rate of ague is due to a real reduction in the prevalence of the disease as a result of more effective prophylaxis and treatment, and how far it may be explained by the increasing admission-rate of simple continued fever, is difficult to gauge exactly, and in this connection a reference may be made to the remarks in the subsequent paragraph upon simple continued fever.

The main causes of death were, as usual, enteric fever and hepatic abscess, the former accounting for 29·7 per cent. and the latter for 11·7 per cent. of the total number of deaths. The mortality from each of the chief diseases, with the exception of heat-stroke, pneumonia, and dysentery, was less than in the previous year.

The main causes of invaliding were, in order, debility, ague, tubercle of the lungs, valvular disease of the heart, disordered action of the heart and syphilis, these causes together accounting for over two-fifths of the total. There was a notable decrease (from 645 in 1904 to 315 in 1905) in the number of men sent home on account of ague, tubercle of the lungs, and syphilis. Only 23 men were invalided for *Bilharzia hæmatobia* as compared with 71 in 1904 and 158 in 1903.

The admission-rate of European troops during 1905 was nearly one and a half times as high as that of native troops, and the constantly sick and invaliding rates were more than twice as high. The death-rates of European and native troops were, respectively, 10·05 and 8·09 per mille.

The average strength of the European troops of the garrison in the Aden Hinterland was 349, and altogether 345 admissions and 3 deaths were reported, giving an admission-rate of 988·5, and a death-rate of 8·60 per mille. Ague, as usual, was the chief cause of sickness, and accounted for 46 per cent. of the total number of admissions. The three deaths were due to pneumonia, hepatic abscess, and intestinal obstruction.

Commands, Divisions, and Stations.—As in 1904, the Northern Command shows lower constantly sick and admission-rates than the Eastern, and the Eastern Command than the Western; and in 1905 these Commands stand in that order also as

regards mortality, the death-rate of the Eastern being considerably higher than that of the Northern. The invaliding rate, as in 1904, was lowest in the Eastern and highest in the Western Command. The admission, constantly sick, death, and invaliding-rates all show an improvement on the corresponding figures of the previous year in *each* Command; but, while the three Commands contribute very equally to the improvement in the constantly sick-rate, the diminution in the admission and death-rates (compared with the figures of 1904) is most marked in the Northern Command. The admission-rate for venereal diseases was highest in the Eastern Command (165·8), and was closely followed by that of the Western (155·4); and in the Western alone was the admission-rate for venereal diseases exceeded by that for ague—the rate for ague in the Western being 162·8 per mille in comparison with 111·4 amongst European troops in India as a whole. The death-rates for enteric fever were approximately the same in the three Commands; those for heat-stroke were about twice as high in the Northern and Eastern as in the Western; those for hepatic abscess were more than three times as high in the Western and Eastern as in the Northern. As regards Divisions, the statistics in the 4th (Quetta) Division were the most unfavourable, showing as they do admission and constantly sick-rates of 1,024 and 60 per mille respectively. The 1st (Peshawar) Division had a higher admission-rate (1,031) but a lower constantly sick-rate (54), and the 9th (Secunderabad) Division with the low admission-rate of 813 had the high constantly sick-rate of 62 per mille. The statistics of the 5th (Mhow), Burma and 3rd (Lahore) Divisions compare most favourably with the corresponding figures of the previous year, but the statistics of the 1st (Peshawar) Division which last year showed the lowest admission and constantly sick-rates (740 and 44 per mille respectively), come next to those of the 4th (Quetta), the most unhealthy of all the Divisions. During 1905, the health of the European troops was most satisfactory in the 2nd (Rawalpindi) and 3rd (Lahore) Divisions. As in 1904, tubercle of the lungs was most fatal among troops in the 6th (Poona) Division, and abscess of the liver among those in the Aden Brigade. Enteric fever was most fatal among troops in the 1st (Peshawar), 4th (Quetta), and 5th (Mhow) Divisions; heat-stroke among those in the Aden Brigade, 1st (Peshawar), 8th (Lucknow), and 3rd (Lahore) Divisions.

Amongst the largest stations, the highest constantly sick-rates were at Lucknow (61·4), Secunderabad (57·9), Quetta (55·4), and Rawalpindi (55); the lowest, at Ambala (48·1). The incidence of enteric fever and hepatic abscess was greatest at Poona and Lucknow, and least at Ambala, Bangalore, and Quetta. In regard to the prevalence of dysentery, however, Quetta came next to Lucknow. Bangalore (20·4), Lucknow (18·4), and Secunderabad (18·3) furnished the highest constantly sick-rates for venereal diseases, and Quetta (7·9) the lowest. Poona, which gave the highest constantly sick-rate for ague (5·4) returned the lowest for simple continued fever (·3); the high rates for simple continued fever of 5·3 and 4·6 were furnished by Lucknow and Quetta, respectively.

Geographical Groups.—The geographical groups which, judged by their statistics, may be regarded as having been the most unhealthy for European troops during 1905, were Bengal-Orissa (IV.), Indus Valley (VII.), Western Coast (X.), Burma Coast (I.), and Central India (VIII.), while at the other end of the scale were the Hill Stations (XII. *a*), Southern India (XI.), and Burma Inland (II.). Comparing the relative position, as to healthiness, of these groups for the past three years (1903-05), it is found that Bengal-Orissa (IV.), Burma Coast (I.), and Central India (VIII.) invariably appear amongst the most unhealthy, and the Hill Stations (XII. *a*) and Southern India (XI.) amongst the healthiest. Omitting Convalescent Depôts (XII.*b*), the highest constantly sick-rates were in Bengal-Orissa (IV.), with 77·3 per mille, Western Coast (X.) with 58·3, and Indus Valley (VII.) with 57·2; the highest admission-rates in Burma Coast (I.) with 1,220·8, Bengal-Orissa (IV.) with 1,160·4, and Indus Valley (VII.) with 1,092·7; the highest death-rates in Bengal Orissa (IV.) with 17·75, Central India (VIII.) with 11·89, and Indus Valley (VII.) with 10·66. The constantly sick, admission, and death-rates of the Hill Stations (XII. *a*) were 45·4, 754·5, and 8·95, respectively, as compared with 52·3, 834·3, and 10·05, respectively, for all India. In these geographical groups the average strength varied from 1,259 in Burma Coast (I.) to 13,724 in Upper Sub-Himalaya (VI.), and in all of them, except four, the admission and constantly sick-rates show a decrease—most marked in Burma Coast (I.), Gangetic Plain (V.), and Central India (VIII.)—on the corresponding figures of 1904. The four groups whose rates compare unfavourably with the previous year's are Southern India (XI.) with an increased constantly sick-rate,

Western Coast (X.) and Hill Stations (XII. *a*) with increased admission-rates, and Indus Valley (VII.) with a considerable increase in both the constantly sick and admission-rates. Ague was most prevalent among the troops located in Bengal-Orissa (IV.) and Indus Valley (VII.); venereal diseases among those in Bengal-Orissa (IV.), Western Coast (X.), Burma Coast (I.), and Southern India (XI.). The mortality from enteric fever was highest in Central India (VIII.), Upper Sub-Himalaya (VI.), Indus Valley (VII.), and Deccan (IX.); in the first two of these groups, it amounted to 41 per cent. of deaths from all causes. Hepatic abscess caused about 17 per cent. of all deaths in Deccan (IX.), Bengal-Orissa (IV.), and Southern India (XI.).

Combining the statistics of all the European troops in India, and comparing the aggregates with those of the previous year, there were, during the year under review, 4,483 fewer men admitted to hospital, 319 fewer men constantly sick, 53 fewer deaths, and 999 fewer men invalided, notwithstanding the fact that the average annual strength of these troops was greater by 260 men. Even if we leave aside the diminished loss from deaths and invaliding, the gain derived solely from the decrease in the number of men constantly sick may be represented as equivalent to the work of 116,435 men for one whole day; this gives an idea of the significance of the above figures.

Influenza.—Influenza was especially prevalent during the year among European troops, the admission-rate, which was 3·1 per mille in 1903, and 4·9 in 1904, rising to 14·2 in 1905. The disease was prevalent in all but one, Southern India (XI.), of the geographical groups, the incidence being greatest in North-Western Frontier and Indus Valley (VII.) and Bengal-Orissa (IV.), which were affected to the extent of 94 and 60 per mille of their strength, respectively. The only other group with a rate above the mean for India (14·2) was Upper Sub-Himalaya (VI.). Some idea of the occasional fluctuation of incidence in the same group from year to year is obtained when it is noted that North-Western Frontier and Indus Valley (VII.), which in 1905 was so severely affected by influenza, was, in 1904, free from the disease. Against 349 admissions with no fatality in the previous year, there were altogether in the year under review 1,014 admissions, with three deaths, reported from 45 stations, of which Peshawar (428), Fort William (97), and Mian Mir (96) contributed 61 per cent. of the total number of admissions. At Peshawar, which, in 1904, furnished no case under this heading, the means by which the disease was introduced could not be discovered. The disease was characterized by the usual symptoms—lassitude, fever, pains in back and limbs, headache, great prostration and debility, and although of a mild type (the case which ended fatally having been complicated by pneumonia) became very prevalent amongst the general population. A careful microscopical examination in each case excluded the possibility of the disease being malaria. Both the intestinal and respiratory varieties were represented; in the former, abdominal pain, nausea, vomiting, and diarrhœa were prominent; in the latter, there was well marked coryza. In all cases convalescence was prolonged and marked by great debility. The epidemic occurred during May and June. For the third year in succession Fort William appears on the list of greatest incidence; the months of maximum prevalence have invariably been August and September. Here also any etiological connection with malaria was excluded. At Mian Mir, influenza was widely prevalent during April and May, and of a mild type, but followed by great debility, and in two cases accompanied by pneumonia.

Cholera.—The troops in the Northern Command remained free from cholera during the year. In India, as a whole, 10 cases, with 9 deaths, were returned during 1905 as compared with 16 cases and 11 deaths in 1904, and 81 cases and 57 deaths in 1903. Of the ten cases during the year, five occurred in November on board the R. I. M. S. "Irrawaddy," which was carrying troops from Mandalay to Rangoon. The cause of infection was attributed to one of these five men having broken bounds and visited a native village, which was afterwards found to be cholera-stricken. All five, who were transferred for treatment to Thayetmyo, died of the disease. Of the other cases, two were reported from Jubbulpore, and one each from Madras, Allahabad, and Dinapore. Cholera is said to have been prevalent in Madras, and to have been introduced by emigrants *en route* to Natal. At Dinapore, the disease was probably contracted in the bazaar, where an outbreak of cholera had occurred after the dispersal of natives from the Sonepore fair. As regards the case at Allahabad, the source of infection was associated with a restaurant outside cantonment limits, but it is not stated if the disease was prevalent in the surrounding district.

Small-pox.—Small-pox was twice as prevalent amongst the European troops during 1905 as during the preceding year, and was reported from all the geographical groups except two—Burma Inland (II) and Bengal-Orissa (IV). The Western Command was chiefly affected, contributing 77 cases (one fatal), while the Northern furnished six cases and the Eastern one only. There were in all 99 cases with one death as compared with 49 cases with four deaths in 1904 and 68 cases with eight deaths in 1903. One or more cases were recorded in 23 stations, the largest numbers occurring in Poona (26), Mhow (19), and Colaba (9). At Poona, the epidemic prevailed from January to May—most of the cases occurring in March, and it is stated that the disease was contracted, in the first instance at least, in the bazaar, where a severe epidemic was raging amongst the natives. All the infected men bore satisfactory marks of vaccination, and none of them had previously suffered from small-pox. No death occurred amongst the 26 men attacked at Poona, while a woman who had not been vaccinated was attacked by the disease and died. The outbreak at Mhow took place in March, and fresh cases continued to occur till June. The disease was prevalent among the native population and the source of infection was traced to the *sadar* bazaar, which is situated near the barracks of the cavalry, who suffered most. None of the patients had previously suffered from small-pox and all had been vaccinated (one man had been vaccinated just a week before he became infected). In the station of Colaba small-pox prevailed from January to March; the disease was severely epidemic in Bombay City, but the source of infection, as regards the troops, was not definitely traced. All the nine men that were attacked had been vaccinated and seven of them revaccinated on one or more occasions.

Ague.—During 1905, a year of abnormally small autumn rainfall, there was exceptionally little malaria among the European troops, intermittent fever being the cause of 13 per cent. only of the total admissions as compared with 19 per cent. during 1904 and 23 per cent. during 1903. The admission-rate for the European army of India as a whole was 111, against 174 in 1904, and an average for the preceding decennium of 311, and the death-rate fell from ·24 in 1904 to ·11 per mille. There was also a coincident diminution in the prevalence of the disease during 1905 among native troops and prisoners, the rates for these (except for that of prisoners in 1896), being the lowest on record. To the reduction in the prevalence of this disease among European troops, all three commands contributed, their admission-rates falling from 202 in the Northern, 212 in the Western, and 129 in the Eastern, to 70, 163, and 113, respectively. The incidence in the Northern thus fell to about one-third of what it was in 1904, and that in the Western, although considerably smaller than in the preceding year, is still the largest in the three commands. The great prevalence of malarial fever in the Western Command was due chiefly to the troops of the 5th (Mhow) Division being particularly affected. Of the ten divisions, the admission-rates were highest among the troops in the 5th (Mhow) Division with 184 per mille of strength, the 1st (Peshawar) Division with 178·9, and the 6th (Poona) Division with 155·6. Among the troops of the Aden Brigade the admission-rate was 286·2 per mille and the death-rate 3·17 against 486·5 and 4·39 per mille, respectively, in 1904.

As regards geographical groups, the greatest prevalence was, in order, in Bengal-Orissa (IV) with an admission-rate of 255·6 per mille, Indus Valley and Frontier (VII), Central India (VIII), Burma Inland (II), and Western Coast (X), and the least in Burma Coast (I) with an admission-rate of 27 per mille, Hill Stations (XIIa) and Upper Sub-Himalaya (VI). Of these, Central India (VIII) and Indus Valley and Frontier (VII) generally take a high place, but the Upper Sub-Himalaya (VI) group which in former years usually accompanied these two (VIII and VII) in the list of groups chiefly affected, appears in 1905 at the other end of the scale with an admission-rate of only 74·6 per mille as compared with 208·8 in 1904. Excluding the Hill Stations, in which the prevalence of malaria depends on the number of infected men arriving from stations in the plains, and comparing 1905 with the previous year, a decrease in the admission-rate is recorded in 49 stations and an increase in 22. If stations in which the annual average strength was below 200 be omitted, the highest rates were recorded at Ahmedabad, Delhi, Thayetmyo and Fort Allahabad, the rates in all being above 400 per mille of strength and being considerably higher than those of the previous year. The admission-rate at Dthalla (Aden Hinterland) was 456 per mille of strength.

The seasonal prevalence of ague is most marked in the Northern Command (May to November) and least in the Western, due doubtless to the effect on the mosquito and the *plasmodium malariæ* of the low temperature during the winter and spring

months in the former command. The influence of temperature on the sexual generations of the malarial parasite and on experimental malaria has been recently investigated by Jancso. Mosquitoes of the species *Anopheles claviger* were infected by being fed on patients suffering from malaria (separate experiments being made for each variety of the malarial parasite), then kept at different degrees of temperature and finally killed, embedded and examined microscopically in sections at stated intervals. If the mosquitoes were kept at 24-30° C., the development of the parasite progressed rapidly and well; at a lower temperature development was prolonged, while at a higher the mosquitoes themselves were unfavourably influenced. If, however, the mosquitoes were kept from the very time of feeding onwards at a temperature below 16° C., no cysts (zygotes) developed; whereas, if, after being kept at a favourable temperature till cysts formed, the temperature was then lowered even much below 16° C., healthy cysts with infective germs were found. The lower limit of temperature permitting the development of the malarial parasites to proceed to the sporocyst stage was 16° C. Jancso also demonstrated that the possibility of infection from the bites of infected mosquitoes is independent of the temperature at which the infected mosquitoes were kept. It would appear, therefore, from these experiments that an infected mosquito even after hibernation may still be infective.

Leaving aside diseases of the nature of relapsing fever, African tick fever, and possibly also yellow fever, in which the specific causative micro-organisms (*spirochætæ*) disappear from the blood with convalescence, immunity in tropical protozoal infections of the human blood, *e.g.*, malaria and trypanosomiasis, is only partial; it is more in the nature of a mutual "tolerance" or symbiosis, the specific protozoon remaining in the body after convalescence. This persistence of the protozoa in the body is possibly due to these small representatives of the animal kingdom being themselves, like their hosts, possessed of the power of producing immune-bodies for self-defence; and this same power may explain the complete failure of serum therapy in these diseases of man. Assuming, therefore, this very natural hypothesis, the methods by which we can hope to combat these diseases are obvious. There is no hereditary immunity or absolute acquired immunity; we cannot rely on the body tissues or fluids being able to rid themselves of these parasites; we have to find some extraneous agent which, while relatively harmless to the host, has a powerful destructive effect on the parasites. For malaria, such an agent we have in quinine. By means of this drug a relative immunity very similar to the acquired immunity of natives may be attained; but the quinine immunity is preferable to the acquired immunity, because natives with the latter, by harbouring the parasite (latent infection), may remain a source of infection long after convalescence. The methods of administering quinine to obtain immunity are various. The various methods of quinine prophylaxis may be divided into two groups, the *rationale* of each group being quite distinct. In the one group, small doses at frequent and regular intervals are given with the object of keeping the blood *always* under the influence of quinine so that the malarial parasite cannot enter the body; in the other group, large doses are administered at intervals of some days in order that quinine may be in such concentration in the blood that the parasites—should they meanwhile have gained an entrance into the body and begun to grow and multiply—are quickly and easily killed, being still in those stages of development most susceptible to the action of quinine. The former is the ideal method, and corresponds closely with natural immunity, but is not practical, for a time comes when owing to some accident or want of foresight the supply of quinine to the blood is not kept up, immunity is lost for a period during which infection may occur, and the administration of small frequently repeated doses, when resumed, may not be sufficient to destroy the parasites that have now established themselves within the human body. For practical prophylaxis the methods of Koch and Morgenroth are most probably the best and quinine prophylaxis can hardly be said to have had a fair trial unless the quinine has been administered in doses of 15 grains on two consecutive days in the week. When anti-mosquito and in particular anti-larval measures are impossible or futile, our only hope of success in combating malaria lies in (1) quinine prophylaxis, (2) segregation and mechanical defence (mosquito-nets, &c.) of healthy and infected alike, and (3) thorough treatment with quinine of malarial patients and cases of latent infection. The importance of rendering natives free from the *plasmodium* is shown by Craig, who found that 62·2 per cent. of adults and 48·3 per cent. of children among the native population in the Philippines were examples of latent infection; and the effect of mosquito-proof wards has been demonstrated by Gorgas on the Isthmus of Panama.

Where quinine prophylaxis is extensively employed as among the European troops in India, the demonstration by the microscope of the malarial parasites in true cases of ague becomes proportionately more difficult; in such cases the increase in the relative number of large mononuclear leucocytes, which seems characteristic of most protozoal blood infections, may be of assistance in coming to a conclusion as to the nature of an illness.

The effect of X-rays in the treatment of malaria has been investigated by Demarchi, who found that these rays have no effect on the course of an attack or on the parasites, but have a favourable action on the chronic large spleen.

Reports from Medical Officers on Malarial Fever.—The more important points brought out by a study of the special malaria reports of stations are here shortly summarized. Of 8,106 cases of malaria among European troops in which the type of fever was diagnosed by clinical methods, 73·78 per cent. were considered by the medical officers to be cases of benign tertian infection, 1·28 per cent. quartan, 5·00 per cent. malignant tertian, ·38 per cent. being cases of "malarial cachexia" and 19·56 per cent. remaining undifferentiated. In 72 stations the microscope was used as an aid to diagnosis and the number of cases in which the diagnosis was thus confirmed was 2,797. In 85·2 per cent. of these, benign tertian parasites were found, in 11·7 per cent. malignant tertian, and in 2·5 per cent. quartan. Quartan fever was recorded in 17 stations and at Port Blair was nearly three times as prevalent as benign tertian. The proportion of malignant to benign tertian infection was highest in Port Blair, Jacobabad, Jubbulpore, Kamptee, and Allahabad, the malignant type being more prevalent than the benign in the first two stations named. At Allahabad, two cases of mixed infection (malignant tertian with benign tertian) were observed. As there were difficulties, however, in differentiating the types of parasites in some cases, the above figures are only approximate. Some medical officers returned cases as malignant tertian only if crescents were found, so the prevalence of this type of fever is probably under-estimated. At Rangoon and some other stations, those cases only in which parasites were found in the blood were returned as malaria, the others being recorded under *simple continued fever;* and the effect of this procedure is well exemplified in the statistics of Mian Mir, where in 1904 and 1905, the admission rates for malaria were 507·4 and 45·7 per mille, respectively, and those for simple continued fever 76·9 and 349·9 per mille, respectively. But the recorded decrease in the prevalence of malaria is by no means wholly accounted for by this change in diagnostic procedure. The influence which the arrival of infected troops may have on the statistics of a station is well seen in the case of Karachi, where the 1st South Wales Borderers, "saturated" with malaria, arriving from Mian Mir in March, caused a rise in the admission rate of the station from 93·6 per mille in 1904 to 245·6 in 1905. At Wellington one man was admitted four times, seven men three times each and eleven men twice each, 19 men thus accounting for 67 admissions. Such results as these show the necessity of segregating and systematically treating with quinine infected troops arriving at a healthy station and also of thoroughly disinfecting (*i.e.*, freeing from parasites) malarial patients and convalescents. In some stations quinine is administered in doses which are far too small, and this is particularly true of the prophylactic dose which, especially in stations which are reputedly malarious, should never be less than 15 grains and should be given on two consecutive days each week during the malarial season. In about eight stations the prophylactic dose was not more than 5 grains given twice a week. At Taragarh, where convalescent and infected arrivals from stations in the plains underwent a systematic course of quinine, viz., 15 grains daily for seven days and then 15 grains twice a week on two consecutive days for a month, there was a total absence of malaria, as compared with 25 admissions (giving an admission rate of 595 per mille) in 1904 when no such precaution was taken. Quinine prophylaxis (15 grains twice a week) was stopped tentatively for a short period at Ahmedabad and the number of admissions for malaria immediately increased. Lastly, the following striking example of the value of quinine prophylaxis is reported from Kamptee: 500 men of the Royal Scots getting 15 grains of quinine sulphate once a week from 1st September to 15th November gave 17 admissions (equivalent to an admission rate of 34 per mille), while 154 men of the 62nd Battery, Royal Field Artillery, that were not taking quinine regularly gave during the same period 20 admissions (equivalent to 129·8 per mille).

At Dum Dum and Dinapore it was observed that quinine tabloids frequently passed almost unchanged through the alimentary canal; quinine was subsequently administered in solution only. Treatment by hypodermic or intramuscular injections

of quinine—chiefly the bihydrochloride, is pretty generally followed and is recognised by many as being more rapid and powerful in its action. This method is found valuable in severe or intractable cases, where the results of administration by the mouth are unsatisfactory, *e.g.*, the desired effect not being produced or, the drug not being tolerated. From Mandalay it is reported that a highly neurotic European woman, six months' pregnant, suffering from malignant tertian fever, received an injection of five grains of quinine bihydrochloride daily until the fever was checked, without the production of any untoward effect on the uterus. In some cases (Dum Dum), where quinine by the mouth was not retained, good results were obtained by giving quinine in rectal injections.

As regards special anti-mosquito measures, the great decrease in prevalence of malaria at Mian Mir is attributed chiefly to the prevention of canal irrigation water from running through cantonments and that at Jubbulpore to the excellent results of the extensive surface drainage carried out near the barracks by the Royal Engineers in 1904. From Peshawar, on the other hand, it is reported that two regiments whose barracks were very near the military grass farm were especially affected during irrigation of this land and had double the admission-rate for malaria of the other regiments not so exposed. The increase of prevalence at Thayetmyo is attributed to the flooding of the country by the Irrawaddy and that at Dum Dum to the neighbouring rice-fields. In Dinapore, however, although anti-mosquito measures were heavily handicapped by the presence of rice-fields all round cantonments, the prevalence of malaria among European troops is less than half, and that among native troops less than a quarter of what it was in 1904. At this station 10 grains of quinine were given under strict supervision on three consecutive days in the week, at first in tabloid form, but latterly, after evidence of the relative insolubility of these preparations, in solution. The decrease of malaria cannot in this instance be accounted for by a change in diagnostic procedure, as admissions on account of simple continued fever have also fallen from 53 in 1904 to 7 in 1905. Consequently, the good results obtained in this station must be attributed principally to quinine prophylaxis and possibly to a less extent to the anti-mosquito measures undertaken. Anti-mosquito operations were carried on methodically and enthusiastically in a number of stations with good results, but in some stations such measures were regarded as impracticable owing to the difficulty of dealing with rice-fields, irrigation canals and other large masses of water in and around cantonments, while in others the efforts of the military authorities were to a great extent rendered futile by the mosquito breeding grounds near cantonments being under the jurisdiction of municipal commissioners who could not be prevailed upon to co-operate. To attain complete success in the campaign against mosquitoes, the systematic concerted action of all residents is necessary. The absence of *anopheles* from Jubbulpore is attributed to the lasting effects of the extensive surface drainage referred to above. In most stations malarial patients were, whenever possible, isolated in special wards and supplied with mosquito curtains; the latter, however, the men did not seem to appreciate. At Ambala, the hospital doors were self-closing and fitted up with wire gauze; at Poona the wards were mosquito-proof. The prevalence of malaria in the Aden Brigade is attributed to the indifference of the men to precautions especially during expeditions into the interior. At Aden itself there is very little malaria, because of the high winds and the absence of vegetation: a few *anopheles*, however, are present—due, in the opinion of the Senior Medical Officer, to the larvæ being introduced with the water supply. In the Aden Hinterland the prophylactic use of quinine was continued throughout the year and the camp on the line of communications was removed to a site a mile further away from the river—measures which have been followed by good results. The effect of methylene blue in malaria was tried at Ahmedabad and Calcutta; in the former station the results are reported as favourable, in the latter as unfavourable. At Kamptee the action of the Italian remedy, *fevrolo*, which is said to have a rapid and powerful lethal effect on the malarial parasite, was tested, but no opinion on its value is expressed. Judging, however, from the temperature charts, this powder does not seem to have any very rapid lethal effect on crescents and apparently after three or four days' administration was invariably displaced by quinine. *Anopheles* were reported during the year in 52 stations in the plains and in 47 of these identification of the species present was attempted. The presence of *A. rossii* was noted in 36 stations, *A. culicifacies* in 20, *A. stephensi* in 7, *A. fuliginosus* in 6, *A. nigerrimus* in 5 and *A. listoni* in 3. Other species mentioned were *A. maculatus*, *A. theobaldi*, *A. barbirostris*, *A. jamesi*, *A. fluviatilis*, and *A. lindesayi*. The

malarial "endemic index" was given by 14 stations but as in all instances except one, the number of children examined was very small, much value cannot be attached to the results.

Remittent Fever.—The admission-rate on account of remittent malarial fever was 2·3 per mille as compared with 3·4 in 1904 and 13·5 for the decennium (1894-1903). This fever was more than five times as prevalent in the Western and Eastern Commands as in the Northern. As regards geographical groups the admission-rate was highest in Burma Coast (I), where, in contrast with those for India as a whole, the rates are on the increase, being 26·2 per mille as compared with 14·6 in 1904 and 6 for the decennium. The greatest diminution in the admission-rate has occurred in Bengal-Orissa (IV), where the rate has fallen from 34·5 for the decennium and 28·4 in 1904 to 4·7 in the year under review. Southern India (XI) recorded no case during the year. The decrease in the admission-rate of European troops during the year has been coincident with a fall in the death-rate, which was ·14 per mille in 1903, ·10 in 1904, and ·01 in 1905.

The seasonal incidence for India, taken as a whole, corresponds closely with that of intermittent fever; and it is impossible to say how far the reduction in the reported admission-rate of remittent fever can be taken as indicating a diminished prevalence of the severer forms of malarial fever. In this connection it may be noted that several medical officers report that the prophylactic use of quinine, even although occasionally it may not produce any great decrease in the incidence of malaria, has some mitigating influence on the severity of the attacks. A considerable part of the reduction, however, is probably due to more careful diagnosis and the more frequent use of the microscope for diagnostic purposes. It is noteworthy that of the five large stations, above mentioned, in which intermittent fever was most prevalent during the year, four—Ahmedabad, Thayetmyo, Fort Allahabad, and Dthalla, have not returned a single case of remittent fever; on the other hand Mhow recorded 39 cases, Port Blair 33, Delhi 20, and Dinapur 12; such facts as these suggest that the diagnostic procedure followed by the various medical officers is a factor influencing remittent fever returns.

Simple Continued Fever.—Since 1902, the admission-rate on account of simple continued fever has increased in a striking manner. The accompanying tabular statement gives the admission-rates of intermittent and the commoner continued fevers and the total admissions of the less frequent continued fevers :—

Year.	Admission-rates per 1,000 of strength.						Actual Admissions.				
	Intermittent.	Remittent.	Simple Continued Fever.	Influenza.	Enteric Fever.	Intermittent, remittent, simple continued, influenza and enteric fevers combined.	Dengue.	Cerebro-spinal Fever.	Malta Fever.	Relapsing Fever.	Dengue, cerebro-spinal, Malta and relapsing fevers combined.
1891–1900 ...	346	15	35	7	24	427	199	2	3	—	204
1901 ...	293	6	24	9	13	345	—	1	5	—	6
1902 ...	247	7	14	2	17	287	298	1	8	1	308
1903 ...	243	4	18	3	20	288	303	—	9	—	312
1904 ...	174	3	24	5	20	226	439	—	6	—	445
1905 ...	111	2	48	14	16	191	415	2	4	—	421

Amongst the former group of fevers, the progressive diminution of the rates for malarial fevers is worthy of note, as is also the coincident increase during the past four years of those for simple continued fever and influenza; amongst the latter, the increase during recent years in the prevalence of dengue, which, however, affects only Madras and Burma, is deserving of notice and is probably explained, as pointed out in this report for 1904, by the more accurate diagnosis of malarial fevers. It is also to be noted that the totals of the ratios of intermittent and the commoner continued fevers show a continuous decline. The admission-rate of simple continued fever during the year was 47·9 per mille, which is double that of 1904, and also considerably greater than that of the decennium 1891-1900, a period during which many other continued fevers, *e.g.*, enteric fever, Malta fever, cerebro-spinal fever, influenza, &c., which were not so well recognised and differentiated as they now are, were doubtless frequently returned under the heading of simple continued fever.

All the commands contribute to this rise in prevalence of simple continued fever, but chiefly the Northern and Western, the admission-rates of which in 1905 were about three times as great as those in the preceding year. As regards geographical groups, all show an increase of incidence except Bengal-Orissa (IV) and Sanitaria (XIIb), the highest admission-rates being in Burma Coast (I) and Gangetic Plain (V) with 136 and 104 per mille, respectively, and the lowest in Western Coast (X) and Central India (VIII) with 2 and 9 per mille, respectively. The stations, with a strength of over 200, at which the highest rates were reported, were Mian Mir (350 per mille), Meiktila (232), Jubbulpore (172), Lucknow (167), Cherat (161), Rangoon (148), and Quetta (146); those at which no case of simple continued fever was reported were Colaba, Wellington, Madras, Bellary, Thayetmyo, Deolali, Kuldanah, Kasauli, Neemuch, Dum Dum, Ahmedabad and Jutogh. For the European troops of India as a whole, the maximum seasonal prevalence during 1905 was from June to October and the minimum during the first three months of the year, and the same seasonal incidence is roughly applicable to each individual geographical group. The most frequent causes assigned for the attacks were excessive atmospheric heat, exposure to the sun without sufficient protection, chills, errors in diet and constipation.

The difference in the prevalence of simple continued fever at Mian Mir in 1904 and 1905 is said to be due to "different methods of diagnosis"; in the former year the microscope was utilised in the diagnosis of only 54 cases of fever as compared with 295 cases in 1905, the usual procedure now, apparently, being to return all cases of doubtful or obscure etiology (the microscopical examination of the blood, and possibly also Widal's reaction, being negative) under the heading of simple continued fever. From a station in Burma, which followed the same procedure in diagnosis, and returned 88 cases of simple continued fever it is reported that the fever was "easily controlled by hypodermic injections of quinine" and that characteristic symptoms of the illness thus recorded were headache, pain in limbs, constipation and a temperature ranging from 102° to 105° for a period of three to seven days. It must be borne in mind that inability to demonstrate the malarial parasite (unless after repeated examination of the blood by an expert) especially now-a-days when quinine prophylaxis is so general, is far from being absolute proof of the non-malarial origin of a fever; and further that even after the exclusion of malaria and enteric fever there are other continued fevers, *e.g.*, influenza, Malta fever, paratyphoid, &c., all endemic in India, which have to be considered in the differential diagnosis before a case is returned under the heading of simple continued fever. At Multan, for instance, some patients who on admission were placed under treatment for malaria were subsequently found to be suffering from Malta fever. The more extended use of the microscope for diagnostic purposes is doubtless largely responsible for the great increase of the reported prevalence of simple continued fever, and this must be taken into account in gauging the significance of the decrease of malarial fevers—intermittent and remittent.

Malta Fever.—There were ascribed to Malta fever four admissions with no deaths during 1905 against six admissions with three deaths in 1904, and nine admissions with no death in 1903. The reporting stations were Ferozepore (February), Quetta (May), Murree (May), and Rawalpindi (September); but the patient at Murree had been admitted from the line of march between Rawalpindi and Ghora Dhakka. The patient at Ferozepore was under treatment for syphilis when the disease developed. He had a total service of six years, four of which had been spent in India; he had never served in a Mediterranean station. The diagnosis was based on the absence of malarial parasites from the blood and the failure of large doses of quinine to reduce the temperature, on clinical grounds—muscular and articular pains and undulant character of the fever, and on the serum test (carried out at the Pasteur Institute, Kasauli) reported as positive for *M. melitensis* in dilutions of 1 in 160, and 1 in 320, and negative for *B. typhosus*. This patient, who was no doubt infected at Ferozepore, was subsequently transferred to Dalhousie. In the case of the patient at Quetta the diagnosis was made on clinical grounds combined with the history of his having served in Malta and having been previously invalided from there for Malta fever. It is not stated when this invaliding had taken place and whether any relapses had occurred in the interval. The blood reaction was not tested, but the clinical picture seems to have been fairly typical. The patient at Murree was most probably infected at Rawalpindi. He had never served in a Mediterranean station, but had been in South Africa. The diagnosis was arrived at on clinical grounds and on the blood reaction, carried out in the

Northern Command laboratory and reported to be "positive for *M. melitensis*, 1 in 50 dilution." The patient at Rawalpindi was at first admitted for malaria (malignant tertian) as the parasite was found in his blood and was treated by intramuscular injections of quinine. As this treatment had little effect on the temperature, which continued very irregular, the serum test with *B. typhosus* was carried out, but with a negative result. The liver also was explored twice with the same result. On the 37th day of illness, the blood tested in the Northern Command laboratory gave a "positive reaction for *M. melitensis* in a dilution of 1 in 200." During his stay in hospital he had a severe hæmorrhage from the bowel, stated to be from an ulcer on the anterior wall on a level with the prostate. Several of the characteristic symptoms and signs of Malta fever were present in this case, but the course of the fever, as presented on the temperature chart, was very irregular. It is not stated if he had served in a Mediterranean station.

Enteric Fever—Recent Investigations.—Taking a general survey of results obtained by a bacteriological examination of the blood, it must be acknowledged that for the early, rapid and comparatively easy diagnosis of typhoid, the method of blood-cultures bids fair to take the first place. Further advantages of this method are its special value in obscure cases and in differentiating typhoid from paratyphoid, also the fact that, *B. typhosus* having been isolated, the diagnosis is assured.

B. typhosus occurs in the urine in from 25 to 30 per cent. only of ordinary cases of typhoid, and is rarely found before the end of the second week, so the bacteriological examination of urine offers but little aid to the diagnosis of this disease. The possible danger, however, of infection from this source is to be borne in mind.

The hopes which had been entertained of the method of fæcal cultures for the diagnosis of typhoid have not apparently been realised. The method is laborious and yields but poor results compared with those of blood cultures.

The presence of typhoid bacilli in the gall-bladder, during convalescence from typhoid and subsequently, has of late received considerable attention.

B. typhosus is sometimes found in sputum in cases of typhoid fever. The sputum should be disinfected in all cases of typhoid fever.

It is evident from experiments that the longevity of *B. typhosus* depends more on actual contact with the sewage microbes than upon contact with by-products capable of diffusion through these membranes and that the duration of life of *B. typhosus* in water is materially affected by the germ contents of its surroundings. Exposed to water highly polluted with saprophytic bacteria, *e.g.*, sewage, the typhoid bacilli cannot survive more than a few days (three to five in the experiment), a period much shorter than that noted in natural unpolluted water. These results, which are said to have been remarkably uniform, strongly support the evidence which is gradually accumulating that *B. typhosus* is a short-lived organism in water under natural conditions.

The incriminating evidence against milk and other foods of spreading typhoid infection has hitherto almost invariably been indirect—by a process of excluding all other possible channels. Konradi, during a typhoid outbreak in the past year, has succeeded in isolating the typhoid bacillus (identified by the usual morphological and biological tests) from suspected milk. Although many epidemics are known to have arisen in this way, on only one previous occasion (in Chicago) has the bacillus been demonstrated in milk. Perhaps the commonest way by which the typhoid bacillus gets into milk is through the use of contaminated water for cleaning milk utensils or for adulteration purposes. Infection by milk can be effectually prevented by pasteurisation.

Although it is not proved that the typhoid bacillus cannot remain for years in earth and then enter the human body and cause enteric fever, the success of the German methods, which have as their sole object to destroy the specific virus as it leaves man, strongly supports the assumption underlying this working hypothesis—namely, that there is no other source of typhoid infection except man. If, as the exponents of these methods maintain, infection arose in other ways, *e.g.*, from soil to man, their efforts would have been futile. The specific virus is present chiefly in the fæces and urine of infected persons, but also to some extent in the vomit, sputum, saliva, nasal mucus, and sweat—practically in all secretions and excretions. Clothes, bedding, furniture, food, utensils, &c., soiled by these, can easily carry infection to others. Contact infection may be (1) immediate or direct, from the body of the

patient to that of attendants, or (2) mediate—through the medium of articles soiled by patients, *e.g.*, clothes, utensils, accoutrements, latrines, &c. In the latter case it is obvious that for contact infection to occur it is not necessary to live in the same room or barrack with or even to have seen or met a typhoid sufferer. Isolated cases separated by intervals of days or weeks, as opposed to the explosive outbreak from a common source of infection such as contaminated water or milk-supplies, are characteristic of infection by contact, where infection occurs in the series of cases at different times and in different ways. Contact infection, however, plays a part in all epidemics; in water-borne epidemics, after the explosive outbreak the contaminated water-supply is cut off, and thereafter all fresh cases of infection are due to contact. Schian, who was in medical charge of the German troops in South-West Africa, reports that segregation on the march or in camp was often impossible and typhoid infection was spread for the most part by contact; that disinfecting measures and particular attention to field latrines were most useful in combating the disease. In connection with typhoid in the United States' Volunteer encampments (1898), Childs states that personal infection, direct or indirect, especially from unrecognised and abortive cases was the chief factor in the spread of the disease. Similarly in the official report on the origin and spread of typhoid in the United States' camps in the Spanish war of 1898, it is held that water was not an important factor, that infected material was transported on the person, clothing and tents, and that infection by contact was all the more frequent as only about half the cases were correctly diagnosed by the army surgeons. For this reason it is strongly urged that all excreta should be disinfected and carted away to some distance from camps. In civil life, we find the same state of things.

Leaving aside occasional abortive and incorrectly diagnosed cases of infection, there are two classes of the public, viz., children and typhoid bacilli-carriers, that, owing to certain peculiarities in their reaction to the typhoid bacillus, are specially dangerous to the community. Children suffer from this disease usually in a mild form, incorrect diagnoses being very frequent, and both from their habits and from their being together in school or at play for a great part of the day are particularly liable to become infected themselves and to infect others; the incidence of the disease is greater among children than among adults. The greater liability of infection from children than from adults has been pointed out by Baginsky, who has studied the course of the disease, as it affects children between one and fourteen years of age, in 88 cases. Frequently the disease, appearing as a feverish dyspepsia, was not recognised. This fact, together with the greater liability of children to soil their surroundings, make it obvious that children are very apt to spread infection by contact. Whenever the floating alien population is increased in an endemic focus, *e.g.*, for public works or military operations, formidable epidemics are almost certain to occur. The peculiarities which make carriers specially dangerous to the public are the difficulty of detecting them, the length of time during which unknown to themselves or others they may be disseminating a virulent specific virus, our inability in the present state of our knowledge to free them from the specific virus and the practical difficulty, almost impossibility, of getting such carriers as are detected to remain under surveillance and bacteriological control and to carry out continuous and efficient disinfectant measures in order to prevent infection being conveyed to others.

Statements regarding the duration of life of *B. typhosus* outside the human body are most conflicting, some maintaining that the bacillus dies after a short period, others that it survives indefinitely. Although under exceptional conditions *B. typhosus* may for a time live, multiply and even gain in virulence, evidence is steadily accumulating that in soil as in water after a comparatively short space of time—especially when these conditions return to normal, virulence declines and the bacillus dies.

The typhoid bacillus is said by Heim to withstand drying for at least 213 days, so this possible method of infection must not be forgotten although infection in this way is probably much less frequent than supposed. In the official report on the spread of typhoid in the United States' camps in the Spanish war of 1898, the opinion is expressed that dissemination by dust was probable to some extent, the camping-grounds being grossly polluted, and that "flies undoubtedly served as carriers of infection." Similarly Childs from a study of the typhoid epidemics in the United States' volunteer encampments (1898) comes to the conclusion that there

was strong presumptive evidence to show that infection was spread to a considerable extent from the latrines by the hosts of flies which swarmed in many of the camps. As regards India, flies, although they do not appear to be the most significant factor in the spread of this disease in the majority of geographical groups, no doubt contribute their quota of cases of infection.

The first clear diagnosis of a case of paratyphoid fever, that is, of a bacterial septicæmia clinically like typhoid but associated with a bacillus quite distinct from Eberth's, was that of Gwyn in 1898, where a "paracolon" bacillus was cultivated from the blood of a patient with all the clinical features of typhoid fever.

In India, paratyphoid no doubt exists, and is possibly not infrequent; but in no case does the causative organism appear to have been isolated and identified. During the past year, a case which was almost certainly paratyphoid fever has been recorded by Major Morgan, R.A.M.C., at Lebong.

Enteric Fever.—Preventive Measures.—As the general and special measures usually adopted in the prevention and suppression of typhoid have been so fully discussed in previous numbers of this report, the following remarks will be confined for the most part to the subject as modified by researches referred to in the preceding paragraphs. It is now generally acknowledged that typhoid is spread by one of the following three ways: (1) contact, (2) water, (3) food (especially milk), and that there is little ground for fearing *B. typhosus* in our surroundings unless it has fallen into water or milk, when we may have mass-infection or epidemics. Water-borne epidemics arise from rivers, water-works or wells being contaminated; mass-infection by milk is relatively rare and is due usually to the milk-vessels having been washed with contaminated water, less frequently by the hands of the sick (especially ambulant cases), of carriers or of attendants on the sick conveying the bacillus into the milk. To stamp out water-borne and milk epidemics the same measures are required as for the prevention of infection by contact, viz., those which attack the virus as it leaves man. Infection by contact may be (1) immediate from the sick patient—especially if wrongly diagnosed, from the ambulant case or from the healthy bacillus-carrier; (2) mediate from articles contaminated by them. One frequently hears of intestinal typhoid, pneumotyphoid, nephrotyphoid, &c., but it must be borne in mind that typhoid is not a local infection of the intestine, lungs or kidneys but a bacillæmia and that the bacillus leaves the human body with all secretions and excretions although chiefly in urine and fæces. In fæces the bacilli are usually most numerous during convalescence and in both fæces and urine, although in their physical appearance there may be nothing to suggest infectivity, the bacilli may be excreted for years after convalescence. Other points to be remembered are that infection with *B. typhosus* may result in many atypical forms of illness which are liable to be wrongly diagnosed and have to be cleared up bacteriologically; that in children typhoid is not an infrequent disease, is usually of a mild type and therefore very often either wrongly diagnosed or left altogether without medical treatment (ambulant). Another interesting, if unusual, source of infection has been described by Dudgeon and Gray, and shows the importance of paying particular attention to bone lesions after typhoid. In this case an abscess appeared in a man's femur two years after an attack of typhoid and led to a sinus which discharged pus containing typhoid bacilli. The man usually dressed the sinus himself but his wife was in the habit of picking up the soiled dressings and burning them. The wife was infected and died of typhoid. It is obvious that proportionate with the increase in our knowledge of the etiology of typhoid has been the increase in magnitude of the difficulties to be faced in the campaign against the disease.

Prompt diagnosis is essential to success and the value of the method of blood cultures in this connection seems established. The agglutination test, however, is by no means to be laid aside although anomalous results occasionally occur. Even typhoid bacilli isolated from the spleen and blood of patients frequently show abnormalities—culturally and biologically as well as in agglutination, although these irregularities gradually disappear by successive passages through animals.

If we find ourselves face to face with an outbreak of typhoid our duty is to try and find the source of infection. Having first excluded the possibility of infection having been imported, attention is directed to water and food, which epidemiological evidence can as a rule easily incriminate or exonerate. If water

and food are free from suspicion, infection by contact alone remains, but still the exact source of infection may be far to seek. The most natural procedure now is to undertake a critical bacteriological examination of all suspicious cases of sickness in and out of hospital (in search of wrongly diagnosed and ambulant cases), paying particular attention to children; and, if no success attend such measures, final efforts must be directed to detecting chronic carriers among those who have at some time or another passed through an attack of typhoid. Here it may be well to draw attention to the fact that it is comparatively rare for carriers to excrete the bacillus in their urine especially when, as usually obtains among troops in India, convalescents from typhoid have undergone a thorough course of urotropine: *B. typhosus* is more likely to vegetate in the gall-bladder and vermiform appendix. Consequently, before convalescents from this disease are allowed to rejoin their regiments, their fæces rather than their urine should be examined bacteriologically several times after recovery at weekly intervals to determine whether or not they are capable of carrying infection. It has been shown that from two to four per cent. of typhoid patients become chronic carriers and Klinger, combining the four best methods of isolating the bacillus from fæces, successfully demonstrated the bacillus in only 80 per cent. of cases. The latter fact indicates not only the probability that the proportion of patients that become carriers is under-estimated but also the uncertainty of detecting by the best means at present in our possession *all* those convalescents who, by becoming carriers, remain constant foci of infection. A system of allowing men recovered from typhoid to rejoin their regiments after a course of urotropine is not sufficient to preclude the presence of carriers, who doubtless exist in all large stations in India;* and latrine disinfection and similar measures by no means safeguard *all* channels and eliminate the danger of infection from this source.

As it is impossible by present methods to detect all sources of infection, for the defence of the susceptible recourse must be had to anti-typhoid inoculation. Vaccines and bacterial extracts have increased in numbers during the past year but most of them are only on trial. Bassenge and Mayer inoculate with a germ-free filtrate of living cultures macerated in distilled water, and report that protection from one injection has lasted six months. Over 5,000 of the German troops going to South-West Africa were inoculated by Kolle and Pfeiffer's method, which consists in inoculating large doses, usually between the clavicle and nipple, in increasing amounts two or if possible three times at intervals of eight days.

Inoculation is, therefore, especially recommended by Morgenroth for soldiers on service in a country where sanitary measures against typhoid cannot be efficiently carried out. At the same time stress is laid on the importance of not sending the inoculated to an infected locality for at least three weeks after the second inoculation. Major Porter, R.A.M.C., has given the statistics of a regiment sent to this country where only two cases occurred amongst 200 inoculated but 60 among 400 non-inoculated. In its interim report the Anti-typhoid Inoculation Committee states that it is satisfied that "the records which are available up to date furnish proof that the practice of anti-typhoid inoculation in the army has resulted in a substantial reduction in the incidence and death-rate from enteric fever among the inoculated." The statistics available for 1904 show that the incidence of typhoid among the inoculated was reduced to at least half of that among the non-inoculated and a similar reduction was observed in the case-mortality of those who contracted the disease after inoculation compared with that among the non-inoculated.

Serum therapy has received a considerable amount of attention during the past year. The French were the first to show that it was possible to obtain an anti-endotoxic serum by injecting nothing but typhoid bacilli.

Enteric Fever: Opinions of medical officers.—Impossible as it has been in the vast majority of instances to ascertain the exact source of typhoid infection, station reports contain abundant evidence to show that so far as European troops in India are concerned water-borne epidemics of typhoid are rare. This doubtless is due in a great measure to the care bestowed on the water-supply in cantonments. There are as usual several isolated cases recorded where it is surmised that soldiers

* From the Central Research Institute, Kasauli, it is reported that two cases of enteric fever at that station were proved to be due to contact with a chronic bacillus-carrier.

have been infected by drinking water from way-side wells and similar sources while on the march, on manœuvres or on shooting expeditions, by drinking aërated waters in bazaars or bazaar milk which has possibly been adulterated with polluted water, or by eating bazaar fruits and vegetables which had been washed in impure water by the native vendors. The chief instance of infection in this manner was that of a draft of 23 men on the line of march to Fatehgarh. Shortly after arrival at that station 12 of these men were admitted to hospital for typhoid. Infection was considered to have been conveyed in the aërated water supplied by natives at one of the camps *en route*. Water of cantonments has been under suspicion in only two or three stations. At Rawalpindi it is said storage (now remedied) was bad, the water having been kept in open-mouthed earthenware *chatties* which were placed on the floor in verandahs; at Poona the water-supply, even after filtration, was regarded with suspicion and recommended to be boiled; at Ahmednagar *B. coli* was found in the soda water manufactured by a regiment. Apart from milk and other articles of food consumed in or brought from bazaars, the authorised supply of these articles (in canteens, coffee-shops, &c.) to regiments has been as a rule above suspicion. The chief exception was the milk-supply of two batteries at Rawalpindi. These two batteries, which had a common dairy in charge of a contractor who kept no cows himself but procured milk from native villages, furnished several cases of typhoid, while a third battery, occupying lines between the other two, had its own dairy under good management and remained free from the disease. At Aden the consumption of oysters taken from the harbour and sold by natives in the bazaar was held responsible for the infection of some men. In not a few stations (Peshawar, Rawalpindi, Quetta, Mhow, Meerut, Campbellpore, Jhansi and Bangalore) dust and flies have been put forward as possible factors in the spread, particularly as the proximity of latrines to cook-houses, stables to barracks, filth-trenches to cantonments, the dusty nature of the country and the small rainfall, favoured such means of dissemination. In Poona, however, dust was considered unimportant, because the greatest incidence was during the rains and the healthiest time of the year was during the dusty season.

One striking point brought out by a study of these station reports is the frequency of imported cases. Apparently most of the men admitted for typhoid in the hill-stations have been infected in stations in the plains or on their way to the hills. In the plains, also, importation is not an infrequent occurrence: 18 at Dinapore, 11 at Agra and 11 at Meerut contracted the disease outside their respective stations. In many stations (Peshawar, Quetta, Campbellpore, Mhow and Poona) typhoid is said to be endemic; in some of them the endemicity is attributed to the disease being prevalent amongst the native population, and the proximity of native villages and bazaars to cantonments and the constant intercourse between them are regarded as sources of danger to British troops. At Peshawar the prevalence of typhoid among natives was confirmed by Widal's reaction; from Sialkot the statement comes that typhoid was very prevalent among native children, but no evidence is given in support of this. In other stations, *e.g.*, Campbellpore, the source of infection was held to have been probably in the barracks themselves, although there had been no case of typhoid in the station so far as known for over 18 months before the outbreak: an opinion, however is not expressed regarding the manner in which the chain of infection had been sustained during that period. Of direct contact infection many instances are given. At Peshawar no less than seven hospital orderlies in attendance on typhoid patients were attacked; at Rawalpindi three nursing orderlies contracted the disease and they in their turn infected several others in their barrack room. Agra, Landour, Jullundur and Mian Mir also furnished cases of infection among attendants on typhoid patients: the hospital orderly who contracted the disease at Mian Mir was employed in the special ward nursing a case which was afterwards diagnosed as typhoid. At Bangalore the first typhoid patient among the troops contracted the disease in hospital where two officers were under treatment at the time suffering from severe attacks of the disease. The following instances explain to some extent the facility with which infection by contact, immediate or mediate, may take place. At Campbellpore when it appeared that an outbreak was inevitable, all the men of the recently arrived drafts were medically inspected. One man was found suffering from malaise and diarrhœa but not so ill as to report sick. He was admitted to hospital and kept under observation; a sample of his blood sent to the Sanitary Officer, Northern Command, for examination was reported as giving a positive

agglutination reaction in a dilution of 1 in 40 within half an hour with *B. typhosus*. This man had suffered from diarrhœa since his arrival in the station but had no fever. Subsequently, he became seriously ill and died after ten days' illness. At the *post mortem* examination healed enteric ulcers were found in the ileum, and the whole intestinal tract was congested. The medical officer of Campbellpore considers it probable that this ambulatory case of typhoid was the origin of the epidemic at that station. At Peshawar it was observed that in many cases symptoms were very slight and the men did not seem very ill although the serum reaction was quite distinct, and that frequently men did not come to the hospital for some days after feeling unwell. Such cases, it is pointed out, are powerful agents in spreading infection. The first man that was attacked by typhoid in the regiment which suffered most severely during the epidemic at Peshawar was ill eight days before coming to hospital and his admission was quickly followed by others from the same and neighbouring barrack rooms. At Cherat there was a well-marked connection between the first typhoid patient, who was ill for some days before coming to hospital, and the next three men admitted. At Karachi, one soldier had been going about for weeks before he reported sick and when admitted to hospital was at first considered to be suffering from ague: he subsequently had a relapse and died. Similar cases were reported from Delhi, Sialkot, Kasauli, Mhow, &c. Ambulant, abortive and atypical forms of typhoid infection are, therefore, not infrequent in India, and men suffering from these types of infection are a real danger to their comrades. At Rawalpindi the arrival of convalescents from the Murree hills was followed by a distinct increase in the number of admissions for typhoid. This led to a careful examination of convalescents with the result that *B. typhosus* was isolated from the urine of several of them. A man, who had been in hospital at Jhansi for some weeks on account of simple continued fever, was sent to Naini Tal for a change. As the history of the case raised suspicions, he was, on arrival at Naini Tal, admitted to hospital for debility, treated with urotropine, kept under observation for 16 days, and then segregated with the other typhoid convalescents. Five weeks after arrival he complained of abdominal discomfort and was admitted to hospital. He had a typical relapse; Widal's reaction was positive. The medical officer at Naini Tal states that he considers all convalescents from simple continued fever arriving from the plains as suspicious if fever had been present for more than two or three days, and that he treats all such cases as typhoid convalescents. Cases like this show the importance, nay, the necessity of viewing all cases of fever as possibly enteric until that disease can be definitely excluded from the diagnosis.

Latrine infection takes a prominent place in many reports. At Peshawar a group of bungalows with their latrines were regarded as infected and on the removal of the troops from this infected area to other barracks the disease ceased: the latrines were of a bad type and situated too near the cook-houses and barracks; the dry-earth system was in vogue and soldiers often omitted to cover their excreta with earth; and flies and dust were plentiful. At Mian Mir infection was considered to have been spread by contact, especially through the medium of infected clothing, bedding and soiled latrine seats: barracks were evacuated; contacts put under canvas, provided with separate latrines and urinals, and their excreta boiled; and clothing, bedding, &c., as well as the evacuated barracks and latrines were disinfected: these measures were followed by good results. At Bangalore the 6th Dragoon Guards were particularly affected, and the only sanitary defect that could be discovered was the proximity of latrines to cook-houses. Barracks and latrines being regarded as infected, the regiment was put under canvas for one month and the vacated barracks and latrines were disinfected. While under canvas there was not a single case of infection, but a couple of weeks after return to barracks the disease broke out again and spread rapidly. The permanent latrines were, therefore, closed and temporary ones constructed on the opposite side of barracks, so as to be as far away from cook-houses as possible, and all excreta were mixed with carbolic acid and boiled. During the six weeks of the year remaining after the adoption of these measures only one man was admitted to hospital for typhoid. In Meerut and Mhow good results seem to have followed the use in latrines of a two per cent. solution of crude carbolic acid instead of dry earth. The following case reported from Naini Tal is of interest. One man had suffered from a severe attack of typhoid at Agra and after being in hospital there for 117 days was sent for a change to Naini Tal where two weeks after arrival he had a relapse.

In most stations diagnosis was confirmed by Widal's test; but in only two stations, apparently, has an attempt been made to isolate the *B. typhosus*. At Sialkot the method of blood cultures was tried in several cases with considerable success; at Karachi bacteriological examinations of blood, urine and fæces were made in each case, but the results are not stated. At Lebong there were only three cases of "typhoid" reported during the year and the three men happened to be in hospital at the same time. Two of these were imported cases; the third case was that of a man who had had no connection with the other two, came from a quite separate part of barracks and had evidently been infected in the station. Widal's test was carried out simultaneously for three patients who were all suffering from a disease clinically resembling typhoid. The blood serum of the two patients who imported the disease agglutinated *B. typhosus* in all dilutions made, while the serum of the locally infected patient entirely failed to agglutinate *B. typhosus*, but agglutinated *B. enteritidis* (Gärtner) in all dilutions in which the test was carried out. This case, which the medical officer regards as one of paratyphoid, would have been of much greater interest and value had the specific organism been isolated and the exact type of paratyphoid bacillus established. In connection with the possible occasional association of paratyphoid with domestic animals, it is worthy of note that at Ambala a strict limit has been placed on the number of dogs, poultry and pigeons kept in barracks.

Enteric Fever: Special sanitary investigations.—Besides an account of inspections and routine laboratory work chiefly concerned with microscopical, bacteriological and chemical examinations, the reports of the Sanitary Officers of Commands for the year 1905 contained the results of investigations of the origin of special outbreaks of enteric fever and other epidemic diseases. For the Northern Command, Major Scott, R.A.M.C., made a special investigation of the typhoid epidemics at Peshawar and Campbellpore. At Peshawar, food and water-supplies were exonerated from all blame: the continuance of the epidemic was regarded as due to "latrine infection, using the term in its broadest sense." The affected bungalows were all in one group, with the latrines not far distant and too near the kitchens. Infection quickly became general in these bungalows because latrines were so placed in relation to bungalows that the latrine which a man from any particular bungalow used depended on which side of the bungalow he emerged, the nearest latrine being invariably the one to which he resorted. The evacuation of this group of bungalows, the thorough disinfection of latrines and the use of crude carbolic acid (three per cent.) instead of dry earth for pans, &c., soon checked the epidemic. Between the first four cases at Campbellpore there was probably a personal connection as all four had supper together on the night prior to the departure of one of the four for Multan. Reasoning by a process of exclusion, the Sanitary Officer comes to the conclusion that here again latrine infection was the cause of the spread, and this conclusion is supported by the later history of the outbreak; for, with the exception of a few ordinary sanitary recommendations for the station in general, measures were restricted to disinfection of latrines and bungalows, and the disease immediately ceased. Two cases are specially mentioned to show the extreme difficulty of determining the immediate cause of an outbreak of typhoid in this country. The first was that of a Gunner who was found to be excreting *B. typhosus* in his urine six months after his discharge from hospital. After a course of urotropine, further attempts to isolate this bacillus from the urine proved futile. The second case occurred at Campbellpore and was an example of the ambulant form of typhoid. The report of Major Elliott, R.A.M.C., the Sanitary Officer of the Western Command, deals specially with the outbreaks of enteric fever at Ahmedabad, Mhow and Poona. At Ahmedabad the source of infection was traced to contaminated mineral waters sold in the bazaar. Samples of the suspected water were analysed and found to contain *B. coli* and *B. enteritidis sporogenes*. The use of waters from this source was discontinued and the outbreak promptly terminated. This epidemic is the only one attributed to contaminated water, which has occurred in the Command during the past five years, the usual method of spread being, in the opinion of the Sanitary Officer, contamination of food by dust and flies which carry the virus from polluted soil. At Mhow all cases had their origin in the station; all seem to have arisen independently, and there was no epidemic prevalence. Typhoid is endemic in this station and consequently latrines, urinals and their vicinity were regarded as probably infected. The dry-earth system of conservancy was discontinued and carbolic acid extensively used: the provision of

a high pressure steam disinfector for use at the station hospital was recommended. The prevalence of typhoid at Poona was due, in the opinion of Major Elliott, not to causes within regimental lines but to the insanitary condition of their surroundings. Typhoid is said to have been frequent among the natives and also among the civil population of the cantonment. No care was taken to disinfect the excreta of such cases and the night-soil carts from the bazaar and other places passed near or through regimental lines and by droppings specifically fouled the roads. Dust and flies were abundant during the year and were regarded as the carriers of infection. Major Aldridge, R.A.M.C., in the report for the Eastern Command draws attention to the difficulty of differentiating species of bacteria which are of intestinal origin from those which are not. In waters there are *coli-like* bacilli, not necessarily of intestinal origin, which, if reliance be placed on the usual tests, may be mistaken for *B. coli*. Similarly, there appear to be several species of bacilli which, if the milk reaction alone be relied on, might be wrongly identified as *B. enteritidis sporogenes*. It is pointed out that "coincidently with the late winter, the usual spring exacerbations of enteric fever were delayed about a month at most stations in the Eastern Command" and that the enteric seasons correspond with the periods of greatest prevalence of flies. At Lucknow special observations were made on the number of flies in barracks, kitchens, latrines and filth trenches and the increase of flies during the latter part of March corresponded very closely, allowing for the incubation period, with the commencement of enteric fever. The total number of flies was undoubtedly less than usual, and, while those found in the lines were mostly common house flies (*Musca domestica determinata*), the only species bred from larvæ and pupæ taken from trenches belonged to the genera *Hylemyia* and *Ulidia*. Apparently, therefore, for some reasons at present unknown, the trenching grounds during the first half of the year were not furnishing the enormous number of flies they usually do and, coincidently, the admissions for typhoid were less than half the corresponding average for the last eight years. Outbreaks of enteric fever at Meerut and Dehra Dun were specially investigated. Stress is laid on two factors which under favourable climatic conditions seem to determine the prevalence of enteric fever among British troops in India: (1) a community peculiarly susceptible on account of age, and (2) a system of sewage removal and disposal eminently suited to the dissemination of *B. typhosus*. In both stations, measures directed against the spread of infection by latrines and clothing were attended with success. The report contains an interesting account of an outbreak of peripheral neuritis, regarded at the time as beri-beri, among British troops at Cawnpore. Although the symptoms were compatible with the supposition that the disease was beri-beri, it was difficult to reconcile many facts with this view. The only other satisfactory explanation of such symptoms occurring in epidemic form seemed to be that they were due to chronic arsenical poisoning and this hypothesis is supported by the facts that a considerable quantity of arsenic was found in the hair of one patient and a trace in the urine of two others, and that all the men attacked were beer-drinkers. On the other hand, no arsenic could be detected in the beer or other articles of food and drink. Samples of the beer that was being issued at the time of the epidemic were, however, not available (the special investigation of the epidemic having taken place some time after the actual outbreak), so the result of the analysis of the beer which happened to be in stock after the epidemic had ceased detracts little from the assumption that the epidemic was one of chronic arsenical poisoning.

Enteric Fever in 1905.—The prevalence of enteric fever among European troops in India during 1905 may now be briefly noted. There were 1,146 admissions and 213 deaths during the year as compared with 1,395 admissions and 267 deaths in 1904 and 1,384 admissions and 293 deaths in 1903. The admission-rate per mille of strength was 16·1 against 19·6 in the previous year. The average duration of a case in 1905 was about 70 days, in 1904 about 68 days, and in 1903 about 54 days. This progressive increase, year after year, in the stay of a typhoid patient in hospital is doubtless due to a more thorough appreciation by medical officers of the danger which convalescents from this disease are to their comrades, if permitted to return to barracks without undergoing a prolonged course of urotropine. That freeing the urinary system thus from typhoid bacilli is not sufficient and does not necessarily completely disinfect the convalescent has been demonstrated. The average number of men constantly sick was 220·50 and the total loss of service due to enteric fever alone was 80,482 days against a constantly sick rate of 256·20 and a loss of 93,769

days in 1904. The death-rate fell from 4·19 per mille in 1903 and 3·76 in 1904 to 2·99 in 1905. The case-mortality is slightly lower than that of the previous year: among every 1,000 patients five more recovered during 1905 than during 1904 and 26 more than during 1903.

There is every reason for believing that this satisfactory improvement is due to the prophylactic measures now in force, in particular those measures which have as their object the limitation of infection by contact, *e.g.*, the segregation of newly arrived drafts and regiments, the early diagnosis and isolation of cases of enteric fever, the attempts to disinfect those who are convalescent from this disease and the disinfection of latrines, barracks, and clothing which may possibly have been contaminated. Much still remains to be done in the way of discovering mild ambulant cases, of recognising atypical forms of the disease and of detecting those convalescents who become carriers in spite of the most thorough administration of urotropine.

Enteric Fever in Commands and Geographical Groups.—The disease was equally prevalent in the three commands but was rather more fatal in the Western than in either of the other two commands. As regards divisions, the incidence was greatest among troops in the 1st (Peshawar), the 6th (Poona) and the 2nd (Rawalpindi) Divisions and least among troops in the 10th (Burma) Division. Of geographical groups, Deccan (IX), Upper Sub-Himalaya (VI), and Indus Valley and Frontier (VII) showed the greatest prevalence during 1905 and of these Deccan (IX) and Upper Sub-Himalaya (VI) always occupy an unenviable position in this respect. On the other hand, the admission-rates in Gangetic Plain (V) and Central India (VIII), which have a very bad record for enteric fever, were only about half those of 1904 or the corresponding decennial means. Hill Stations (XIIa) show a progressive improvement, the admission-rate which was 29·4 per mille for the decennium 1894-1903 having fallen to 14·7 in 1904 and 10·9 in 1905. Burma Coast (I) and Western Coast (X) together did not furnish more than 1·1 cases per mille of strength. The following tabular statement, of the monthly incidence, based on the total admissions during the past ten years, in the geographical groups throws a little light on the possible part which dust and flies play in the dissemination of enteric fever in the different groups.

If dust is a very significant factor in the spread of the disease, the incidence should be relatively low during the rains. Applying this test to the different geographical groups we find that dust can be a possible factor of *significant* importance in only four groups: Gangetic Plain (V), Upper Sub-Himalaya (VI), Indus Valley and Frontier (VII), and Convalescent Depôts (XII-*b*): in the first two groups (V and VI), however, where there was a decided increase of incidence during August, dust cannot by any means be the only possible significant factor. As regards flies, it is difficult in so extensive a country as India, which includes regions with vastly different climates, to lay down general tests relative to the prevalence of flies, about the life-history of which we have still much to learn. Precise information (obtained from observations extending over several years) on the relative monthly prevalence of these insects in the stations of India would be of great help in gauging the importance of flies in the dissemination of typhoid. In the present state of our knowledge the easiest test to apply is a comparison of the relative frequency of admissions for enteric fever in the two seasons of the year when flies are (1) most common and (2) least common. Flies are numerous everywhere in the months of August and September, and probably in most stations they are more numerous then than in any other two months, but it is only in groups VIII, IX, XI, and XIIa that the incidence of enteric fever is relatively heavy during these months: in one group (viz., VII) the incidence of enteric fever is lowest in these months and February. Flies are

Seasonal incidence of Enteric Fever during the Decennium 1896–1905, *in stations in the Northern Command and in seven other Indian stations in which the disease is very prevalent.*

not specially numerous in Northern India in the winter, and yet in group VII (North-West Frontier and Indus Valley) the incidence of enteric fever then is comparatively high. From the table on page 49 it will be observed that the winter incidence of this disease in the most northerly Indian stations is far from being insignificant. The same table also shows the seasonal incidence in seven other Indian stations, outside the Northern Command, which generally suffer severely from this scourge. It is hoped that the figures given may be of some assistance to officers in medical charge of these stations in forming an opinion on the extent to which the seasons of greatest prevalence of flies coincide with those of heaviest incidence of enteric fever.

Enteric Fever in Stations.—From 25 stations as against 28 in 1904 admission-rates of over 20 per mille were reported and among these the following may be noted with their admission-rates per mille:—

In Group VI.		In Group V.		In Group VIII.		In Group IX.	
Campbellpore	190·3	Fatehgarh	89·2	Indore	44·1	Poona	43·2
Meerut	57·3	Dinapore	32·8	Nowgong	28·0	Secunderabad	27·3
Lahore	49·6	Lucknow	27·8	Jhansi	26·8	Kirkee	24·0
Amritsar	24·5			Mhow	23·0		
Rawalpindi	23·9						
Mian Mir	22·1						
Ferozepore	20·2						

The list also includes Peshawar (4·27), Barrackpore (21·0), and Quetta (20·5), as well as five hill-stations and convalescent depôts. There was a total absence of enteric fever from 20 stations, including Pachmarhi, where in 1904 there were 24 admissions and four deaths among 162 men. All stations in group (VIII) Central India show a decrease (compared with last year's figures) except Indore and Nowgong, and, similarly, all stations in group (V) Gangetic Plain, except Fatehgarh and Allahabad. The monthly incidence of enteric fever among European troops shows how rarely a sudden outburst, so characteristic of an epidemic due to infected water or food, occurs in Indian stations; the evidence is strongly suggestive of "contact infection."

Relation of Enteric Fever to Age and Length of Residence in India.—In 1905 as in previous years the greatest liability to suffer and die from enteric fever fell upon the age-period 20 to 25 and upon the first year of Indian service. The extent of this liability is indicated by the fact that nearly 73 per cent. of the total admissions at all ages were among men up to 25 years of age and that nearly 64 per cent. of the total admissions were among men during their first two years of Indian service. The tendency to a rise in the admission rates for the higher age-period continues: in 1905 the admission-rate of men over 35 years of age was 4·2 per mille as compared with 4·0 in 1904 and 3·5 in 1903. On the other hand, there has been a break in the progressive rise of the admission-rate for the higher service-periods: the admission-rate during 1905 of men with five years' service and upwards was 6·9 per mille as compared with 11·4 in 1904 and 10·2 in 1903.

Plague and some other General Diseases.—Among European troops in India in 1905 there were recorded 13 cases of plague with four deaths as compared with two cases with no fatality in 1904 and 12 cases with two deaths in 1903. Of the 13 cases reported during 1905, seven cases with two deaths were at Aden, three with one death at Bombay, one (fatal) at Benares, and one case each at Fatehgarh and Port Blair. At Aden all seven cases occurred between the 19th and 24th April, the source of infection having been traced to the regimental coffee-shop which was infested with plague-stricken rats. The town, in which the disease was prevalent, had been out of bounds for two months before the outbreak among the troops. At Bombay the exact source of infection was not ascertained, but the disease was prevalent among the natives in the town. The patient at Benares was probably infected in the *Sadar* bazaar which suffered severely from plague and was separated from barracks by a road only. The medical officer at Fatehgarh suggests that the patient at that station was infected by his favourite cat which was known to have killed rats in the infected quarters of hospital servants. The case at Port Blair was imported from Rangoon. There were altogether 13 admissions with one death on

account of measles, the majority occurring at Quetta and Lucknow. Erysipelas accounted for 36 cases with three deaths. Of the 46 admissions with five deaths on account of beri-beri, no less than 25 with three deaths were recorded at Aden and 10 with one death at Cawnpore. The outbreak at Cawnpore, which occurred between August and October, has already been referred to. At Aden the disease is said to have been unknown among British troops in that station until the arrival of a regiment from Burma about six years ago. The incidence is said to have been high among beer-drinkers but no trace of arsenic was detected on analysis of the beer. The patients were between 24 and 36 years of age and about half of them lived in the upper stories of barracks and about half in the lower. The spread of the disease is attributed to infected buildings under the favouring conditions of heat and moisture. (The native troops at Aden furnished one case of beri-beri.) There were 415 cases of dengue with one death as compared with 439 cases with one death in 1904 and 303 with one death in 1903. The disease was practically confined to two stations in the Secunderabad Division and two in the Burma Division, Fort St. George (Madras) with 48 cases and Rangoon with 354 cases being the chief places affected. At Rangoon no case of dengue was recorded from January to May: most cases occurred in November. In 1902 the epidemic at Rangoon lasted from March to July, so the seasonal incidence varies considerably. With regard to the cases reported in December, the medical officer states that the diagnosis is open to question as the main clinical features of dengue were absent. The blood of a large number of these was carefully examined for malarial parasites but with negative results. *Bilharzia hæmatobia* accounted for 22 admissions during the year against 63 in 1904 and 318 in 1903. The number of stations in which a case or cases were detected was 11 as compared with 26 in the previous year and 33 in 1903. The number of men invalided for this cause fell from 71 in 1904 to 23 during the year under report.

Tubercle of the Lungs.—The admission-rate of European troops in India on account of tubercle of the lungs fell from 2·8 per mille in 1904 to 2·1 in 1905. The admission-rate of the Western Command (3·0) has increased while those of the Eastern and Northern Commands have decreased, that of the Northern Command (1·7) being less than half what it was in the previous year. The stations reporting the largest number of admissions were Poona with 14, Rangoon with 10, Quetta with 9, and Lucknow with 8. The death-rate fell from ·38 in 1904 to ·28 per mille during 1905, and the number of men invalided for this disease from 223 to 116. The death-rates from tubercle of the lungs of European troops, native troops, and prisoners during the year were in the proportion of 5, 9 and 65, respectively, as compared with 5, 7 and 48, respectively, in 1904.

Pneumonia and other Respiratory Diseases.—In 1905 the admission and death-rates for pneumonia were 4·1 and ·63 per mille, respectively, as compared with 3·4 and ·52 in 1904, the corresponding decennial means being 4·3 and ·62, respectively. There were 296 admissions and 45 deaths from this disease in 1905 against 240 and 37 in 1904. Both admission and death-rates were greatest in the Northern Command and least in the Eastern. The three groups in which pneumonia is usually most prevalent among European troops are (VII) Indus Valley and Frontier, (VI) Upper Sub-Himalaya, and (XIIa) Hill Stations, and in 1905 these same three groups head the list with admission-rates of 7·1, 5·4, and 5·8 per mille, respectively, (IV) Bengal-Orissa coming next with 4·7, and (VIII) Central India next with 4·4. Compared with the previous year there was an increase in the admission-rate in all the geographical groups except (I) Burma Coast, (XI) Southern India, and (XIIb) Convalescent Depôts, and the increase was greatest in (IV) Bengal-Orissa and (VII) Upper Sub-Himalaya. Excluding Fort Lahore and Khandalla where the strength was low, the highest admission-rates for the year were recorded at Dum Dum with a rate of 17·8 per mille and an average strength of 281 men, Quetta with 13·1 and a strength of 2,590 men, Nowshera with 12·5 and a strength of 720 men, Ambala with 11·7 and a strength of 2,314 men, Agra with 10·5 and a strength of 1,146 men, and Peshawar and Thayetmyo each with 10·2 and strengths of 1,663 and 488, respectively. For India as a whole the months of greatest prevalence are, as a general rule, December, January, and February, and those of least prevalence July, August, and September; for the year under report most cases occurred in December and fewest in July.

There was an increase in the admission-rate on account of "other respiratory diseases" as compared with the previous year, viz., 23·0 per mille against 21·4 but the death-rate was only ·06 per mille as compared with ·10. The increase in the admission-rate is shared by all three commands, but the greatest rise was in the Eastern Command where the rate rose from 17·3 to 22·5. The highest rate (26·4) was in the Western Command. The geographical group in which these diseases were most frequent during the year was (IV) Bengal-Orissa, (XIIb) Convalescent Depôts coming next; and the stations (excluding those with an average strength below 150) which recorded admission-rates above 40 per mille were Dum Dum, Quetta, Wellington, Kuldana, Karachi, Kasauli, and Maymyo.

Dysentery and Diarrhœa.—There has been a slight increase in both the admission and death rates on account of dysentery, the rates being 13·4 and ·46 per mille as compared with 12·6 and ·42 in 1904. Native troops show a slight increase in the admission-rate, but a decrease in the death-rate; while, as regards prisoners, there was a decrease in the admission rate, but an increase in the death-rate. Of the three Commands the disease was most prevalent and fatal during the year among European troops in the Western and, as regards Divisions, it was most prevalent in the 9th (Secunderabad), 4th (Quetta), and 5th (Mhow). The death-rates were highest among troops in the 10th (Burma) and 5th (Mhow) Divisions. Among geographical groups, the disease was most prevalent and fatal in (I) Burma Coast. Excluding stations with a strength below 150, the highest admission-rates were recorded at Dthalla (Aden Hinterland) with a rate of 65·9 per mille among 349 men, Barrackpore with 55·9 among 286 men, Rangoon with 40·2 among 1,119 men, and Aden with 33·8 among 947 men. For the European Army as a whole the months of greatest prevalence were July, August, and September, and those of least prevalence February and March.

While dysentery was the cause of 959 admissions and 33 deaths, diarrhœa accounted for 1,087 admissions with no fatality. The admission-rate for diarrhœa was 15·2 per mille as compared with 13·1 in the previous year. The disease was most prevalent in the Eastern Command, and least in the Northern. As regards geographical groups, the highest rates were in (XII *a*) Hill Stations, (I) Burma Coast, and (IV) Bengal-Orissa. In the first mentioned are included the two stations with the highest ratios, *viz.*, Ranikhet (108·6 per mille) and Lebong (49·4), as well as Dagshai and Chaubattia, which have ratios of 42·2 and 33·8 respectively.

Hepatic Abscess.—The admission and death-rates on account of abscess of the liver were 2·1 and 1·18 per mille as compared with 2·6 and 1·36 in 1904. In the Northern Command the admission-rate was only about half, and the death-rate only about a quarter of the corresponding rates in either the Western or Eastern. The disease was most prevalent among troops in the 6th (Poona), 8th (Lucknow), 5th (Mhow), and 9th (Secunderabad) Divisions, and the Aden Brigade. The death-rates were highest in the Aden Brigade and 5th (Mhow), 8th (Lucknow), and 9th (Secunderabad) Divisions. As regards geographical groups (IV) Bengal-Orissa still retains an evil reputation, which during the year under report is shared with (X) Western Coast, (XII *b*) Convalescent Depôts and (IX) Deccan. There were in all 153 admissions with 84 deaths recorded during 1905 as compared with 185 admissions and 97 deaths in the previous year. One or more cases were reported from 60 stations, and, excluding Poonamallee and Calicut, where the average strength was low, the highest admission-rates were at Barrackpore (three cases with one death), Dinapore (five cases with four deaths), and Kasauli (three cases with two deaths). At Lucknow, however, there were thirteen admissions with five deaths, at Poona eleven admissions with two deaths, at Secunderabad seven admissions with five deaths, at Wellington six admissions with four deaths, and at Jhansi five admissions with four deaths, these being stations with an average strength of about 1,000 and over. There was a history of dysentery in eight of the thirteen cases at Lucknow, in four of the seven cases at Secunderabad, in two of the eleven cases at Poona, and in two of the five cases at Jhansi, but in none of the three cases at Barrackpore; in a few instances hepatic abscess is mentioned as having occurred after enteric fever. As in previous years, multiple abscesses were found in the majority of the fatal cases.

Alcoholism.—There were 197 admissions with 11 deaths from alcoholism during 1905 against 220 admissions and 9 deaths in the previous year, the corresponding average numbers for the decennium ending 1904 being 250 and 8, respectively;

compared with the decennial average rates, there was, in 1905, a fall in the admission-rate, but a rise in the death-rate. The liability to death from alcoholism has a distinct tendency to rise with age and length of residence in India.

Venereal Diseases.—The recorded admission-rate for all forms of venereal disease in 1905 was 153·7 per mille of strength as compared with 198·5 in 1904, the actual numbers being 10,966 in 1905 and 14,113 in the previous year. The constantly-sick-rate was 15·3 per mille against 17·5 in 1904, and the average period during which a case remained in hospital was 36·26, which is an increase of 4 days on the average stay in hospital of each patient during 1904. The total loss of service, however, was 397,584 days as compared with 454,206 days in 1904 and 572,864 days in 1903. The non-efficiency, thus reckoned, due to detention in hospital on account of venereal diseases during 1905, amounts to about five times the loss incurred on account of enteric fever.

There were 13 deaths (·18 per mille of strength) attributed to venereal diseases during 1905 as compared with 15 (·21 per mille) in 1904 and 10 (·14 per mille) in 1903; the number of men invalided for this cause was 83 (1·16 per mille) as compared with 199 (2·80 per mille) in 1904 and 213 (3·02 per mille) in 1903.

All three Commands record a diminution in the admission-rates for venereal diseases; but for 1905, as in the previous year, the Eastern Command heads the list with an admission-rate of 165·8 per mille followed by the Western with a rate of 155·4. The admission-rate in the Northern Command was only 116·1 per mille, while the rate among troops outside this Command was 166·7; the corresponding figures for native troops are 18·8 in the Northern Command and 19·9 outside this Command. As regards Divisions, venereal diseases were most prevalent in the 10th (Burma) with an admission-rate of 206·9 per mille of strength and the 9th (Secunderabad) with a rate of 194·0, and least in the 1st (Peshawar) with a rate of 74·1 per mille and the 2nd (Rawalpindi) with a rate of 105·7 per mille. Comparing 1905 with the previous year, the Divisions which show the greatest reduction in prevalence of these diseases are the 10th (Burma), the 7th (Meerut), and the 4th (Quetta).

Admission-rates of over 200 per mille were reported from 21 stations, 4 of which had an average strength below 100 men; and, if we omit Lower Topa (377·8 per mille) where the average strength was only 45, the highest rate was recorded at Maymyo (338·1). Excluding stations at which the average strength was less than 100, venereal diseases in the Northern Command were most prevalent at Kasauli (with an admission-rate of 214·7 per mille), Mian Mir (168·7) and Kuldana (158·6), in the Western Command at Deolali (265·5), Bombay (265·0) and Purandhar (246·2), in the Eastern Command at Fort William (283·5), Barrackpore (241·3) and Lebong (229·4), in the Secunderabad Division at Madras (266·8), and Bellary (263·7), and in the Burma Division at Maymyo (338·1), Rangoon (253·8), and Shwebo (175·2). The stations with an average strength of over 100 which in a comparison with the previous year showed the greatest improvement were Maymyo, Meiktila, Agra, Muttra, and Neemuch; altogether 78 stations out of a total of 104 recorded a diminution in the prevalence of venereal diseases during the year under review.

The admission-rate on account of gonorrhœa was 74·8 per mille of strength (the total number of admissions for gonorrhœa being 5,338), and that on account of soft chancre 43·3 per mille as compared with rates of 95·3 and 54·2 per mille, respectively, in 1904. Eight men, as compared with 24 in the previous year, were invalided during 1905 for gonorrhœa.

Syphilis accounted for 2,537 admissions, 13 deaths, and 75 invalidings as compared with 3,488 admissions, 15 deaths, and 175 invalidings in 1904. The admission-rate fell from 49·1 per mille in 1904 to 35·6 per mille in 1905. The figures, however, for 1905 are not strictly comparable with those of 1904 and previous years, as in June, 1904, changes in the methods of classification and treatment of this disease came into force, and these changes considerably affect the statistical returns. Between 1st June, 1904, and the end of that year, the names of 2,947 men were placed on the "syphilis register," but this number doubtless includes the names of many men who contracted the disease in previous years. The number of men whose names were placed on the register during 1905 was 1,470; this represents the number of men who came under treatment for syphilis for the first time, and may be taken as approximately the number of cases of fresh infection during the year, and yields a rate of about 21 per mille. A large number of men required admission or re-admission to hospital while undergoing treatment as out-patients, and the number of men who had relapses after being struck off the register was 35. The average

number of days each case was under treatment was 261. As regards the methods of treatment, the most common whether in or out of hospital were: (1) by injection; (2) by the mouth; of the men in hospital, roughly speaking, for every five treated by injection four were treated by the mouth, while of the men treated out of hospital, for every one treated by the mouth seven were treated by injection.

That there has been in recent years a real reduction in the amount of venereal diseases in the European Army of India, there can be no doubt, although from the changes in classification (for statistical purposes), the introduction of the "syphilis register" and the treatment of some cases as out-patients, it is difficult as yet to gauge the amount of real reduction in prevalence, and the relative values of the causes at work in producing this diminution. At first sight it might be thought that, if in consequence of the above changes admission statistics were not comparable, from the combined death and invaliding rates we should be able to get some approximate idea of the real reduction in the prevalence of these diseases. This, however, is not so. There has been a steady and, latterly, fairly rapid fall in the number of invalidings, and this has not been accompanied by any increase in the number of deaths in India, but the more prolonged and thorough treatment now undergone by those found suffering from venereal diseases may, in a great measure, explain these favourable results.

Medical officers attribute the prevalence of venereal diseases to the youth and ignorance of the soldier, and the difficulty experienced in controlling infection outside cantonments, particularly on the line of march between stations. For limiting the spread of infection reliance is placed chiefly on (1) medical inspections of troops to detect infected men, and place them in hospital; (2) prolonged and thorough treatment, which diminishes the number of sources of infection; (3) the enlightenment of the soldier on the ravages and dangers of venereal diseases; and (4) the encouragement of games, &c., to occupy his leisure hours pleasantly. By such means as these it is reasonable to hope that the prevalence of venereal diseases may be considerably reduced.

Heat-stroke.—The death-rate from heat-stroke was ·77 per mille against ·49 in 1904 and ·77 in 1903; and as usual the mortality is highest in the Northern Command and lowest in the Western. The total number of deaths recorded under this heading was 55 as compared with 35 in 1904 and 54 in 1903. The stations which furnished the largest numbers during 1905 were Peshawar (6), Mian Mir (5), Agra (5), Rawalpindi (3), Lucknow (3), Bombay (3), and Aden (3).

Suicide.—The average annual number of suicides reported in the decade 1891-1900 was 19, and in 1905 the number was 24, of which eleven were by gunshot, four by cut-throat, four by multiple injuries (including fracture of the skull and dislocation of the spine), three by drowning, one by hanging and one by oxalic acid poisoning.

Invaliding.—From the whole European Army in India 1,508 men (21·24 per mille of strength) were invalided in 1905 as compared with 2,507 (35·27 per mille) in the previous year; the chief causes of loss by invaliding have been mentioned. The ratio per 1,000 of strength ranged from 28·61 in the Western Command to 14·95 in the Burma Division. Of the 152 men invalided for debility, 106 were under 30 years of age, and 80 had been less than four years in India; and of the 116 men invalided for tubercle of the lungs 98 were under 30 years of age and 64 had been less than three years in India. Of the total number of men invalided, 47 per cent. were under 25 years of age, an age-period which included 52 per cent. of the total strength; and 82 per cent. of all invalids were under 30 years of age, an age-period which included 85 per cent. of the total strength. As regards length of residence in India, 25 per cent. of all invalids had less than two years' service in this country, and 65 per cent. less than five years; the proportion to total strength of men with under two years' service in India was 43 per cent., and of those with under five years' service 84 per cent. The loss from invaliding among men in the lower age-periods, and also among men of shorter service in India, was not so great as in the previous year.

Officers.—The average strength of commissioned officers with European troops in India in 1905 was 2,323, and of these 1,608 had been under medical treatment. 123 were invalided, and 21 died during the year. The admission, invaliding, and death-rates were lower than in the previous year, while the constantly-sick-rate remained the same. The admission rates for ague, remittent fever, tubercle of lungs,

dysentery, diarrhœa, and hepatic affections show a decrease as compared with the figures for 1904, but those for small-pox, enteric fever, simple continued fever, and respiratory diseases an increase. There were six deaths from enteric fever, the chief cause of mortality, giving a rate per mille of 2·58 which is practically the same as in 1904, and is lower than the rate for the troops (2·99). There were 55 cases of dysentery without a fatality against 63 cases with one death in 1904. There was only one case (non-fatal) of each of the diseases, hepatic abscess and plague. As compared with the incidence on troops the following diseases were more prevalent in proportion to strength; influenza, enteric, remittent, and simple continued fevers, dysentery, diarrhœa, and congestion of the liver, while the officers suffered less than the men from small-pox, ague, hepatic abscess, venereal diseases, tubercle of the lungs and other respiratory diseases. Enteric fever, debility, ague, and dysentery were the chief causes of invaliding.

Women.—There was a distinct improvement in the health of the women during the year under review. The average strength was 3,375, which is an increase of 155 on that of 1904. There were, in all, 2,183 admissions and 37 deaths, giving admission and death-rates of 646·8 and 10·96 per mille respectively, as compared with rates of 697·2 and 12·42 in the previous year; the constantly-sick rate (27·9 per mille) showed an improvement of 2·7 per mille. The average admission, constantly sick, and death rates for the decennium 1894-1903 were 873·4, 36·5, and 15·68 per mille respectively. The chief causes of admission to hospital were, as usual, debility, the diseases peculiar to women, and ague, which together accounted for 61·88 per cent. of the total number of admissions for all causes. Of the 37 deaths five were due to enteric fever, five to childbirth and abortion, and three each to small-pox, tubercle of the lungs, and dysentery. Among the commands and independent divisions, the highest admission-rate was recorded in the Eastern Command, and the lowest in the Burma Division, the highest death-rate in the Western Command, and the lowest in the Secunderabad Division.

Children.—There was less sickness among the children during 1905 than in either of the three previous years, but the constantly-sick rate was exceedingly high, and the death-rate, although much lower than that in 1902, was considerably higher than those of the two previous years. In 1905 the average strength was 5,154, the admission-rate 405·9 per mille, the constantly-sick rate 29·3, and the death-rate 38·8. The chief causes of sickness were respiratory diseases, ague, and diarrhœa, which together accounted for 36 per cent. of the total number of admissions for all causes. There was a considerable diminution in the prevalence of ague, measles, and eye-diseases as compared with 1904. Out of a total of 200 deaths, 38 were attributed to debility and immaturity at birth, 32 to respiratory diseases, 25 to diarrhœa, and 15 each to teething and convulsions, which taken together account for 63 per cent. of the total mortality. There were 26 admissions with two deaths from enteric fever, giving a case-mortality of 8 per cent., while for diarrhœa there were 207 admissions and 25 deaths, yielding a case-mortality of 12 per cent. Among the exanthemata to which children are specially liable there came under treatment during the year 46 cases of chicken-pox, 12 of measles, 2 of rubella, 5 of scarlet fever, and 9 of small pox; there were also 23 cases of whooping cough, 12 of mumps, 8 of diphtheria, and 3 of dengue. Sickness was greatest among children in the Secunderabad Division, and mortality among those in the Eastern Command; sickness and mortality were both least in the Burma Division. Immaturity at birth was the cause of death in 37 per cent. of the total mortality among children under six months. Of the two children who died of enteric fever, one was between five and ten, and the other between ten and fifteen years of age.

Native Troops.

(For Statistical Tables, see pages 134 to 137.)

Sickness and Mortality in 1905.—The health of the native troops during 1905 was exceptionally good. The average strength, excluding those on duty in China and Somaliland, was 123,434, as compared with 124,055 in 1904. The following statement gives a tabular view, enabling an easy comparison to be made, of the statistics of sickness, mortality and invaliding during 1905, the previous year, and the quinquennial period from 1897 to 1901. The rate of admission into hospital was slightly higher than in the previous year, but the constantly-sick and death-rates were the lowest on record. The low death-rate is all the more noteworthy as, out

Native Troops.	All Causes. Ratios per Mille.		
	1897–1901.	1904.	1905.
Admissions	794·4	603·2	607·1
Constantly sick	30·5	23·8	23·2
Deaths	11·92	8·46	8·09
Invalids	12·66	12·98	9·02

of the total number (998) of deaths during the year, 185 were killed at Dharmsala by the collapse of buildings during the earthquake. The slight increase in the admission rate compared with that of the previous year, which was a record figure, was entirely due to the greater prevalence of the minor and less usual causes of sickness; simple continued fever, "other respiratory diseases," dysentery, remittent fever, diarrhœa and enteric fever, alone, showed increased rates, but the increase arising from the combined rates of these diseases amounted to only 18·5 per mille, while the decrease under the heading of intermittent fever alone was 22·9 per mille. A reduced mortality was recorded during the year from all the principal diseases with the exceptions of enteric fever, circulatory diseases and diarrhœa.

The chief causes of sickness in 1905 were intermittent fever, dysentery, "other respiratory diseases," venereal diseases, simple continued fever and pneumonia, in order of their relative prevalence, the first mentioned accounting for 28 per cent. and dysentery for nearly 5½ per cent. of the total number of admissions from all causes. The admission-rate for simple continued fever was more than double that of the previous year, with the result that for the year under review this disease occupies a more important place than pneumonia as a cause of sickness. The chief causes of death were pneumonia, remittent fever and tubercle of the lungs, these diseases accounting for 23·5 per cent., 6·9 per cent. and 6·2 per cent., respectively, of the total number of deaths from all causes. The number of men invalided for discharge from the service during 1905 was 1,113, as compared with 1,610 in 1904, the chief causes of this source of loss being, in order, debility, tubercle of the lungs, rheumatism, venereal diseases and intermittent fever.

The native troops suffered less than the European troops from influenza, small-pox, enteric fever, simple continued fever, diarrhœa, hepatic affections and venereal diseases, but they suffered more from each of the other chief causes of sickness, as also from scurvy.

The average strength of the China Garrison during the year was 1,753. The chief causes of sickness were influenza, "other respiratory diseases," ague, dysentery and venereal diseases, these together accounting for nearly half of the total number of admissions to hospital; the admission-rate fell from 351 per mille in 1904 to 339 per mille in 1905. There were altogether eight deaths, giving a ratio per mille of 4·56; five deaths were attributed to tubercle of the lungs. The average annual strength of the Somaliland Field Force was only 525 as compared with 2,521 in 1904; admissions numbered 596 and deaths two, yielding rates of 1,135 and 3·81 per mille, respectively, against 930 and 17·06, the corresponding figures in 1904. The most prevalent diseases were ague, dysentery and diarrhœa, the admissions for ague alone amounting to 367, *i.e.*, 62 per cent. of the total from all causes. The Aden Column Field Force, the average strength of which was 695, suffered chiefly from ague, dysentery and diarrhœa, these three together accounting for 64 per cent. of all admissions. The actual number of admissions to hospital was 908, which gives a rate of 1,306 per mille; there were two deaths, one from pneumonia and the other from ague. The Sikkim-Thibet Mission Force, having an average annual strength

of 358, reported 293 cases of sickness and 12 deaths during the year, the ratios per mille per annum being 818·4 and 33·52 respectively. Malaria, dysentery and diarrhœa were the chief causes of sickness, and remittent fever was responsible for seven out of the twelve deaths.

Commands and Divisions.—Among the commands in 1905, the Northern had the highest admission, constantly-sick and death-rates, due as regards the chief causes of sickness to the relatively great prevalence of pneumonia, "other respiratory diseases," simple continued fever, and tubercle of the lungs, and as regards the chief causes of death, to the excessive mortality from pneumonia, tubercle of the lungs and remittent fever, as well as to the results of the earthquake at Dharmsala. The Eastern Command, although showing higher admission, constantly-sick and death rates than in the previous year, still ranked first in order of healthiness. Among the ten divisions, if we omit the 3rd (Lahore) Division, in which the constantly-sick and death rates were very high—due to the number of men injured and killed at Dharmsala at the time of the earthquake—morbidity and mortality were greatest in the 2nd (Rawalpindi) Division and lowest in the 9th (Secunderabad) Division.

Geographical Groups.—Judged by the statistics of sickness during the decennium 1891-1900, the geographical groups most unfavourable to the health of the native troops are, in order, Assam (III), Burma Inland (II), Bengal-Orissa (IV), Hill Stations (XII), and North-Western Frontier and Indus Valley (VII), the admission-rates in all of these having been over 1,074 per mille, and the constantly-sick-rate over 35 per mille as compared with 852 and 32, respectively, the corresponding decennial means for India as a whole. During 1905 it is found that these same groups, with the exception of Burma Inland (II), were the most unhealthy. For the past two years Burma Island (II) has had admission and constantly-sick rates lower than the corresponding means for India: in this group the average strength during 1905 was only 2,916, against 6,083, the average for the decennium 1891-1900, so doubtless during the year under review the troops, thus greatly reduced in numbers, were better housed and in more favourable surroundings than formerly; this may in part explain the fall in the admission rate from 1,165 for the above decennium to 539 in 1905. It should be noted that the average strength in Assam (III) was only 949 and in Bengal-Orissa (IV) 2,558, while in Hill Stations (XII) and North-Western Frontier and Indus Valley (VII) the average strengths were 20,224 and 17,946, respectively. The admission-rate for intermittent fever was highest in Bengal-Orissa (IV) and Assam (III); that for dysentery in Bengal-Orissa (IV), Burma Coast (I), Assam (III), and North-Western Frontier and Indus Valley (VII); that for remittent fever in Bengal-Orissa (IV) and Hill Stations (XII); that for influenza in Bengal-Orissa (IV); that for pneumonia in North-Western Frontier and Indus Valley (VII). Enteric fever was most prevalent among native troops in Upper Sub-Himalaya (VI) and Hill Stations (XII). Excessively high rates for simple continued fever, ranging from 57·3 to 20·7 per mille were returned from the five groups Southern India (XI), Burma Coast (I), Hill Stations (XII), Bengal-Orissa (IV) and Deccan (IX); in all these groups the rates reported for 1905 were much higher than the corresponding figures for 1904, and this rise in the rates for simple continued fever was almost invariably coincident with a considerable fall in the rates for malaria. The maximum prevalence of tubercle of the lungs was, as usual, in Upper Sub-Himalaya (VI), Hill Stations (XII) and North-Western Frontier and Indus Valley (VII). The highest death-rates during 1905 were returned from Hill Stations (XII) and Western Coast (X), in which groups there was a high mortality from each of the three chief causes of death among native troops—pneumonia, tubercle of the lungs and remittent fever.

Hill stations below 5,000 feet in height are, as a general rule, the most unfavourable to the health of native troops as regards both sickness and mortality; but during 1905 the death-rate was exceptionally high (27·13 per mille) in hill stations above 5,000 feet, owing to the number of men killed in the catastrophe at Dharmsala. If the deaths at Dharmsala are excluded, the death-rate in hill stations above 5,000 feet is only 7·72 per mille as compared with 9·87, the rate in hill stations below 5,000 feet. It is worthy of note that, as regards the native army, the health of troops located in hill stations above 5,000 feet in height compared unfavourably, both in 1904 and 1905, with that of troops located in the plains.

Stations.—In 1905 there were 36 stations with an average strength of over 1,000, but in only one of these, namely, Dera Ismail Khan, were the admission and death-rates excessive, the rates of this station being 967·0 and 16·52, respectively. The

rates of admission for malaria, dysentery, pneumonia, debility and diarrhœa at this station were all high; and, of the 38 deaths, 22 were due to pneumonia and 5 to remittent fever. Among the regiments with the most unhealthy records during the year were the 11th Rajputs and the 75th Carnatic Infantry, both stationed in Mauritius, who suffered severely from malaria, as did also the 120th Rajputana Infantry at Baroda; and the 1-6th Gurkha Rifles at Abbottabad—ague, simple continued fever, mumps and bronchitis being the chief causes of sickness.

Influenza.—The admission rate on account of influenza fell from 1·8 per mille in 1904 to 1·5 in 1905, and the death-rate from ·02 to *nil.* This disease was much less prevalent, during 1905, among the native troops than among the European troops or prisoners. The largest numbers of admissions were recorded among the troops at Mardan, Karachi, Fort William and Ferozepore, the Northern and Eastern Commands being chiefly affected. The months of greatest prevalence were January, February and September, the high incidence in September being due to all the cases at Fort William having occurred in that month.

Cholera.—There were among the native troops during 1905, only eleven cases of cholera with seven deaths, as compared with 27 cases and 22 deaths in 1904, and 135 cases and 80 deaths in 1903. The Northern Command reported during the year only one case (at Abbottabad) which ended fatally; the Western Command three non-fatal cases (all at Jhansi); the Eastern Command four cases (two at Dinapore and two at Allahabad), all fatal; the Secunderabad Division three cases (all at Madras) with two deaths; the Burma Division returned no case under this heading. The three cases at Madras occurred in the 88th Carnatic Infantry; the disease was present in epidemic form in the city. At Allahabad both cases occurred among the men of the 9th Bhopal Infantry and the source of infection could not be traced; one man was attacked while returning from leave and died a few hours after rejoining his regiment. The case at Abbottabad was attributed to the consumption of infected water or food on the line of march; cholera was prevalent in the surrounding district. Nothing is said by the medical officers regarding the other cases, which occurred in the 12th Pioneers at Jhansi and the 5th Light Infantry at Dinapore.

Small-pox.—There were 77 admissions and one death from small-pox during the year as compared with 56 admissions and three deaths in 1904; the rates per mille of strength for 1905 were ·6 and ·01, respectively, the former being higher but the latter lower than the corresponding mean rates for the decennial period 1891-1900. The Western Command was chiefly affected, returning 50 cases out of the total of 77; the Eastern Command and the Burma Division reported no cases. The largest number of admissions (seven) at any one station was recorded at Bombay, all among the men of the 113th Infantry; there were six cases at each of the three stations Dera Ismail Khan, Mhow and Kirkee. The six cases at Dera Ismail Khan, occurred during August among the men of the 55th (Coke's) Rifles; five had been vaccinated and one bore the marks of small-pox. The men attacked at Mhow had not been vaccinated since enlistment, but bore marks of vaccination in childhood. The patients at Kirkee had contracted the disease in Poona; all had been vaccinated, and one was deeply marked by an attack of the disease which he had undergone many years before. In many reports no remarks are made on the source of infection or on the presence, on the men attacked, of the marks of vaccination or of a previous attack of the disease. In 1905, as in the previous two years, small-pox was less prevalent among the native than among the European troops; the disease is much more fatal to the latter.

Ague, Remittent Fever and Simple Continued Fever.—Intermittent fever accounted for over 28 per cent. of the total number of admissions from all causes in 1905, but the admission-rate, which was 358 per mille in 1901, 274 per mille in 1902, 247 per mille in 1903 and 194 per mille in 1904, fell in 1905 to 171 per mille, which is less than half the mean (349) for the decade 1891-1900. Of the three commands, the Western was chiefly affected during the year, the next place being taken by the Eastern; all three showed a decrease in prevalence as compared with the previous year, but the decrease was greatest in the Northern Command. The admission-rates recorded in all but two of the twelve geographical groups were lower than in 1904, the two exceptions being Bengal-Orissa (IV) and Southern India (XI); the incidence of the disease was highest in Bengal-Orissa (IV), Assam (III), Central India (VIII) and Western Coast (X). Taking India as a whole, the month of greatest prevalence was November, December coming next, and fewest cases occurred,

as usual, in March. October has been, as a general rule, the month of greatest incidence in previous years; the unusual incidence in 1905 may be due to an outburst of infection, or relapses, after the issue of quinine for prophylaxis had been stopped for the season. The stations (excluding those with an average strength under 100) at which the highest admission-rates were recorded, were Baroda (1,319 per mille), Sibi (711), Fort William (662), Ahmedabad (630) and Port Blair (605); at Mauritius the rate was 1,715 per mille of strength. The admission-rate of the troops composing the Aden Column Field Force fell from 1,823 per mille in 1904, to 688 in 1905, 478 admissions having been recorded in the latter year on an average strength of 695 men. At Baroda the 120th Rajputana Infantry were very severely affected, the admission-rate being more than four times as high as in the previous year. The medical officer states that the civil dispensary books show that the disease was also exceptionally prevalent among the civil population, and reasoning by a process of exclusion he has come to the conclusion that the small Vishwamintri River, running in the Gaekwar's territory and coming within a quarter of a mile and to the windward of the lines, is the chief breeding place of mosquitoes. There were many stagnant collections of water along the river side, especially at places where cattle were watered, and it was impossible to deal effectually with these breeding grounds of the mosquito. The increase in prevalence of the disease at Mhow was said to be due to many infected men having arrived from Tibet and the Aden Hinterland; the great increase at Meerut (also Deesa, Indore, &c.) was similarly regarded as due to the arrival of infected troops from very malarious stations. The two regiments located in Mauritius suffered severely; out of a total of 2,000 admissions to hospital, from all causes, of the men of the 11th Rajputs, there were 1,749 admissions on account of malaria (1,658 for ague and 91 for remittent fever); and out of a total of 1,170 admissions from all causes of the men of the 75th Carnatic Infantry, there were 848 on account of ague. The heavy incidence is ascribed to the heavy rains and the general unhealthiness of the island during the year; the men were provided with mosquito nets and quinine was issued prophylactically.

Remittent fever was more prevalent during 1905 than in the previous year, but less prevalent than in 1903, the admission-rate during the year being 8·4 per mille. The death-rate (·56 per mille), however, was less than that (·71) of the previous year; the disease accounted for about 7 per cent. of the total number of deaths from all causes during 1905 as compared with about 8 per cent. in 1904, about 9 per cent. in 1903 and about 10 per cent. in 1902. The incidence of the disease was, as usual, heaviest in the Northern Command, the Eastern Command coming next; the groups most affected were Bengal-Orissa (IV), Hill Stations (XII), Indus Valley and Frontier (VII) and Gangetic Plain (V). The regiments which furnished most admissions were the 11th Rajputs in Mauritius, the 3rd Brahmans at Dibrugarh, the 62nd Punjabis at Fyzabad, the 45th (Rattray's) Sikhs at Nowshera and the 2-4th Gurkha Rifles at Pathankote. The seasonal incidence of this disease is very inconstant; during 1905 the prevalence was greatest in July and least in February.

The admission-rate on account of simple continued fever, which in 1903 was 3·5 per mille and in 1904 was 6·7, rose in 1905 to 14·3, the actual numbers admitted to hospital being 441 in 1903, 829 in 1904, and 1,768 in 1905. Among geographical groups, the highest rates during the year were recorded in Southern India (XI), Burma Coast (I), and Hill Stations (XII). Most cases were reported in the month of June, and fewest in February and March. The regiments returning the greatest number of admissions under this heading were the 1-6th Gurkha Rifles at Abbottabad (174 cases), the 1-1st Gurkha Rifles at Dharmsala (178 cases) and the 2nd Queen's Own Sappers and Miners and the 69th Punjabis at Bangalore (151 and 123 cases, respectively), three stations thus furnishing 626 admissions out of a total number of 1,768 recorded throughout India during the year.

Enteric Fever.—In the whole native army of India, 130 cases with 35 deaths were attributed to enteric fever during 1905, as compared with 70 cases with 16 deaths during 1904, 80 cases with 27 deaths during 1903, 50 cases with 12 deaths during 1902 and 26 cases with 15 deaths during 1901. The admission-rate was 1·1 per mille in 1905 and the death-rate ·28 against rates of ·6 and ·13, respectively, in 1904. The disease was most prevalent in groups VI (Upper Sub-Himalaya), XII (Hill Stations) and IX (Deccan); I (Burma Coast), II (Burma Inland), III (Assam) and IV (Bengal-Orissa) returned no case. There were nearly twice as many admissions as in the previous year, but there were fewer reporting stations and regiments; 29 stations and 44 regiments recorded one or more cases in 1905 as

compared with 33 stations and 46 regiments in 1904. Of the total number of admissions for enteric fever, 31 per cent. (40 cases) were returned from Dehra Dun, 22 per cent. (29 cases) from Abbottabad, 6 per cent. (8 cases) from Peshawar and also from Bolarum; no other station recorded more than four cases. The regiments which reported most cases were the 1-9th Gurkha Rifles (18 cases), the 2-9th Gurkha Rifles (18 cases), the 1-6th Gurkha Rifles (14 cases), the 2-6th Gurkha Rifles (13 cases), and the 1-2nd Ghurka Rifles (8 cases) among Ghurkas, and the 99th Deccan Infantry (6 cases), the 12th Pioneers (4 cases) and the 38th Dogras (4 cases) among sepoys of other classes; in 24 regiments only one case was recorded during the year. The special incidence of this disease among Gurkhas was particularly marked, the disease having been very prevalent among them during the year under review; of 130 cases reported, 83 occurred among Gurkhas (6·0 per mille) and 47 only among sepoys of other classes (·44 per mille). The 83 cases among Gurkhas were reported from nine regiments, whereas the 47 from sepoys of other classes were distributed among 35 regiments. Enteric fever during 1905 was twice as prevalent and twice as fatal among native troops as among prisoners; but, although the disease was nearly fifteen times as prevalent among European troops as among native, the death-rate among the former was only about eleven times as high as among the latter (the case-mortality among native troops was 27 per cent., that among European troops was 19 per cent.).

According to the reports of medical officers, many cases were typical clinical pictures of enteric fever; intestinal hæmorrhage and perforation occurred in several instances, but phlebitis and thrombosis were not observed. Widal's reaction was carried out in the majority of cases; but no *post-mortem* examination seems to have been made. The exceptional prevalence of the disease among the Gurkhas in 1905 is attributed by the regimental medical officers to the large proportion of recruits present owing to recent changes in the number and composition of battalions and the consequent increase in the proportion of young men in the regiments (the majority of those who suffered from the disease were recruits). The exact source of infection in any of these outbreaks was not discovered and medical officers were content to blame water, milk, and food in comprehensive manner. At Dehra Dun the medical officers report that the surroundings of the cantonment were insanitary, being polluted to a great extent by the excreta of native villagers; that the river's banks especially were fouled in this way; that the river water was obviously contaminated by sewage; and that flies were abundant at the time when enteric fever was prevalent in the regiments. The medical officer of the 99th Deccan Infantry at Bolarum states that some cases of enteric fever in the bazaar had come to his notice while acting as civil surgeon, and that the outbreak in the regiment occurred after this and was probably caused by specifically infected water, milk, or food obtained in the bazaar.

Malta Fever.—There was a decided increase in the recorded prevalence of Malta fever, 43 cases with one death having been recorded during 1905 against five cases in 1904, eight cases in 1903, and four cases in 1902. The only month in which no case was reported was May. At Rawalpindi 17 cases occurred, 16 in the 31st Punjabis and one in the 11th Lancers, the chief incidence being in July: at Ferozepore 14 cases, eight in the 14th Sikhs, and six in the 15th Sikhs, with the largest number of admissions in December: at Multan in the 27th Punjabis 10 cases (one fatal), six of which were admitted in April. Besides these the 28th Punjabis at Delhi and the 19th Lancers at Ambala furnished one case each.

As regards the epidemic at Rawalpindi, the diagnoses were made on clinical grounds taken in conjunction with the results of the serum test carried out at the Pasteur Institute, Kasauli. In most cases, on admission to hospital, a search for the malarial parasite was made but invariably with a negative result, and quinine in large doses had no effect on the temperature. In one instance the blood was sent to Kasauli three times and each time the serum reaction was negative both for *M. melitensis* and *B. typhosus*; but after three months' persistent fever of a decidedly undulant type, and intractable neuralgia, the blood was sent a fourth time when the serum was found to agglutinate *M. melitensis* in a dilution of 1 in 80. The medical officer of the 31st Punjabis reports that the admissions took place in batches, suggesting infection by food-stuffs. Several of the men had drunk unboiled goats' milk, which, diluted with water, was commonly used in the lines as a cooling drink. Twelve of the 16 cases were Sikhs, a suggestive fact in view of the special addiction of Sikhs to drinking unboiled goats' milk. At Ferozepore the course of the disease in most of the cases was characteristic and the serum

reaction carried out at Kasauli in all cases positive, although the attempt to get a growth of the micro-organisms by inoculating agar tubes with splenic blood was not invariably successful. The medical officer of the 14th Sikhs is of opinion that the disease was "most probably contracted from the 27th Punjabis, who brought it with them from Somaliland. Four goats were found infected in the lines and destroyed." The Sikhs had taken over the lines from the 27th Punjabis. On the other hand, the medical officer of the 15th Sikhs expresses the opinion that "the disease has probably been present for years but went undiagnosed." It is noteworthy—in connection with the suggestion that mosquitoes carry Malta fever—that the disease was most prevalent in Ferozepore in the month of December. The epidemic in Multan is of special interest as it was from the blood (splenic puncture) of one of these patients that the *M. melitensis* was first isolated in India and the disease thus shown, beyond dispute, to be endemic in this country. The medical officer of the 27th Punjabis reports that he is unable to trace the source of infection and continues,—"I note in the annual report of 1904 the medical officer states that several cases of very protracted fever were returned under remittent fever and he considered this diagnosis unsatisfactory. I may add that I sent specimens of blood from cases which were shown as remittent fever in 1904, and 13 out of 16 gave the serum reaction of Malta fever." The solitary case at Delhi presented very indefinite symptoms and signs and suffered from a continuous remittent pyrexia for about 29 days. There was nothing characteristic in the temperature chart. Vigorous treatment with quinine and diaphoretics had no effect on the temperature and the patient rapidly became weak and anæmic. Eventually, a sample of his blood was sent to the Pasteur Institute, Kasauli, and the serum, while having no effect on *B. typhosus*, agglutinated the *M. melitensis* in a dilution of 1 in 1,280. The Director of the Pasteur Institute, who then sent the medical officer in charge of the case some agar tubes for insemination with the patient's splenic blood, reported that he got a good growth of *M. melitensis* from the tubes thus treated. The course of the disease in the Ambala case was fairly characteristic, and the serum reaction carried out at the district laboratory at Ambala was stated to be "complete and speedy in dilutions of 1 in 40 and 1 in 80."

In analysing the medical reports on these cases of Malta fever, the frequent absence of one or more of the characteristic signs and symptoms is striking; in fact the clinical course of some cases—say the solitary case at Delhi—could hardly have raised any suspicion of this disease, unless by a process of exclusion, and yet this case gave a positive agglutinative reaction in a dilution of 1 in 1,280. The most constant features were a protracted persistent pyrexia unaffected by quinine, marked constipation, and muscular and articular pains usually noted as neuralgic and rheumatic. It must be remembered, however, that even in Malta the variability of the course of the disease has led to a division into clinical types or groups, *e.g.*, the sub-acute or chronic type with frequent relapses; the type with sharp fever lasting only for a short time and ending in rapid convalescence with none of the usual complications of the sub-acute or chronic type, &c. It is not, therefore, surprising to find one or two amongst those 43 cases with a sharp bout of fever lasting only a week or ten days and not leading to much debility or anæmia. Such cases in the absence of the serum test would be very liable to wrong diagnosis. The temperature curve, even when fever was protracted, frequently showed no trace of undulations; it was often very irregular and sometimes remittent, sometimes intermittent. The neuralgic and rheumatic symptoms were frequently absent; the liver and spleen were not always enlarged; and often no sweating was observed. Many cases of this disease must occur, which require the serum test to distinguish them from malaria, typhoid, simple continued fever, rheumatic fever, and gonorrhœal rheumatism; and in all differential diagnoses, where Malta fever is a possibility, the serum test should be carried out. It is now recognised that, if carefully performed with a reliable strain of *M. melitensis*, recently isolated and known to agglutinate with normal human serum only in very low dilution, this test is quite trustworthy.

Plague.—There was a great decrease in the incidence of plague among the native troops in 1905: in 1898 there were 94 cases with 54 deaths; in 1899, 76 cases with 45 deaths; in 1900, 56 cases with 29 deaths; in 1901, 70 cases with 41 deaths; in 1902, 192 cases with 95 deaths; in 1903, 184 cases with 115 deaths; in 1904, 187 cases with 111 deaths; and in 1905, only 79 cases with 46 deaths. Out of the total of 165 stations occupied by native troops during

1905, about 111 were situated in districts where plague was prevalent among the general population, yet in only 27 of these did cases occur among the troops. The largest number of admissions reported from one station was 13 at Bangalore, nine cases occurring in the 2nd Queen's Own Sappers and Miners and four in the 30th Lancers. The only other stations furnishing more than five cases among native troops were Poona, in which ten cases occurred among the men of the 94th (Russell's) Infantry and one case among the men of the 121st Pioneers; Santa Cruz, in which nine cases occurred among the men of the 104th Rifles; and Nasirabad, in which seven cases occurred among the men of the 116th Mahrattas. No other corps returned more than five cases; fifteen reporting stations and eighteen regiments recorded only one case each.

Cerebro-Spinal Fever.—The decrease which has been noted in recent years in the prevalence of cerebro-spinal fever among native troops has been very conspicuous during the year under review, only one case (fatal), viz., in the 57th Rifles at Peshawar, having occurred in the whole native army during 1905, against six cases with four deaths during 1904 and also in 1903, 18 cases with 17 deaths during 1902, and 28 cases with 21 deaths during 1901.

Scurvy.—There has been a marked diminution in the prevalence of scurvy during the year, the total number of admissions into hospital for this disease in 1905, being only 213, which gives a ratio of 1·7 per mille as compared with ratios of 4·0 per mille in 1904, 2·4 per mille in 1903 and also in 1902, and 3·2 per mille in 1901. In these figures the statistics of troops serving in Somaliland are not included; in 1905 these troops returned only one case as compared with 899 cases in the previous year. The statistics, however, of the Aden Column Field Force are included in the above figures and this force, which furnished 94 admissions for this disease in 1904, recorded two admissions only in 1905; to this reduction is due in part the low rate recorded during the year under review. About 64 per cent. of the 213 admissions for this disease were recorded among troops in the Western Command and 18 per cent. among those in the Northern; and, as regards geographical groups, over 39 per cent. of the admissions occurred among troops in Hill Stations (XII) and over 9 per cent. among troops in Central India (VIII), these being the two groups which usually furnish most cases. The five regiments which were most affected all belonged to the Quetta Division of the Western Command; these regiments were the 101st Grenadiers (14 cases), 106th Hazara Infantry (12 cases), the 124th Infantry (12 cases), the 126th Infantry (12 cases) and the 105th Mahrattas (11 cases). The medical officer of the 101st Grenadiers at Quetta states that all the 14 men admitted for scurvy had contracted the disease in Somaliland or at Aden, that two of the men had to be invalided as they had lost their teeth and were unfit for further service, and that fresh onions had a very beneficial effect on the course of the disease.

Tubercle of the Lungs.—It is satisfactory to note that during 1905 both the admission and death-rates on account of tubercle of the lungs among native troops have shown an improvement on the exceptionally low rate recorded in the previous year. The accompanying table shows the admission and death-rates for this disease (1) among the native troops of India as a whole and (2) among Gurkhas, for each year of the past decade. The admission-rate of the native army during 1905 was

Years.	Admission and Death Rates for Tubercle of the Lungs.			
	Native Army of India as a whole.		Gurkha regiments.	
	A	D	A.	D
1896	2·5	·65	7·4	3·59
1897	2·6	·79	10·3	5·55
1898	3·5	·63	13·1	4·45
1899	3·3	·68	15·4	5·09
1900	3·7	·78	14·4	4·34
1901	4·2	·84	13·1	3·95
1902	4·3	·80	15·6	4·24
1903	5·9	·68	28·9	2·88
1904	3·9	·51	10·6	2·66
1905	3·1	·50	6·1	1·58

the lowest recorded since 1897, and that of Gurkhas was the lowest recorded in the decade 1896-1905. The decrease in the death-rate is still more marked; the rates for 1905 of both the Native army as a whole and of the Gurkhas were the lowest in the decade, the rate of the latter being exceptionally low. The decrease in prevalence of this disease was most marked in the statistics of the Assam (III) group, the admission-rate in this group falling from 7·5 per mille in 1904 to 1·1 per mille in 1905: Upper Sub-Himalaya (VI) recorded the highest admission-rate (4·7 per mille) during the year, the Hill Stations (XII) coming next with an admission-rate of 4·6 per mille. The chief factor determining the position of the various groups, relative to prevalence of this disease, is the number of Gurkhas located therein; and the decline during 1905 in the rates of groups that usually occupy a high position on this list was due chiefly to the great diminution in prevalence of the disease among Gurkhas, and, in the case of Assam, to the reduction in the number of Gurkhas located in that group. As regards commands, the incidence of the disease during 1905 was, as usual, greatest in the Northern Command with an admission-rate of 5·4 per mille as compared with a rate of 3·1 per mille for India as a whole. The admission-rate during the year of troops, excluding Gurkhas, in the Northern and Eastern Commands was 4·2 per mille, that of Gurkhas serving in the same two commands was 5·2 per mille, the latter ratio being less than half the corresponding figure for the previous year; the death-rate, however, of Gurkhas in these two commands, although much lower than in previous years, is still more than twice as high as among troops of other classes located in the same commands. In the whole native army of India during 1905, this disease accounted for 385 admissions and 62 deaths, of which 85 admissions and 22 deaths occurred among Gurkhas. These figures give admission and death-rates for the native army of India, excluding Gurkhas, of 2·7 per mille and ·36 per mille, respectively, and rates for Gurkhas of 6·1 per mille and 1·58 per mille, respectively. It is noteworthy that in 1905 for the first time the regiment recording the highest number of admissions for tubercle of the lungs was not a Gurkha regiment. The regiments with the largest numbers of admissions were, in order, the 21st Punjabis (16 cases) the 2-1st Gurkhas (9 cases), and the 1-2nd Gurkhas, the 7th Gurkhas, the 12th Pioneers, and the 113th Infantry (8 cases each). The 21st Punjabis were stationed in Northern China for the first four months of the year and after arrival in India were at first located at Multan and subsequently at Jhelum: the medical officer reports that the disease was contracted in China and was aggravated by the dust storms of that country, and that the disease was more frequent and fatal among Dogras than among other classes of sepoys in the regiment. The exceptional incidence of the disease among the 7th Gurkhas is attributed by the medical officer to the unusual hardships and the severe weather to which the men were exposed at Dharmsala and Bakloh.

There were six cases returned as non-tuberculous phthisis during the year, as compared with three in 1904, six in 1903, and 23 in 1902.

Pneumonia and other Respiratory Diseases.—The admission-rate for pneumonia in 1905 was 12·5 per mille and the death-rate 1·90 per mille as compared with 11·7 and 2·32 per mille, respectively, in 1904. The increase in prevalence, compared with the previous year, was due to the greater incidence of the disease in the (VI) Upper Sub-Himalaya and (IV) Bengal-Orissa groups, each of which records an increase in the admission-rate of about 5 per mille over that of 1904. Despite its diminished fatality this disease was still the chief cause of death among native troops in 1905, accounting for over 23 per cent. of the total number of deaths. The North-West Frontier and Indus Valley (VII) retained its position as the group in which pneumonia was most prevalent during the year, Upper Sub-Himalaya (VI) and Central India (VIII) coming next; in (XII) Hill Stations the disease was not so prevalent as in previous years. The months of greatest incidence were, as usual, January, February, and December. Among stations with an average strength over 100 the highest admission-rates were recorded at Kherwara (91·2 per mille) and Kotra (46·7 per mille), both in the (VIII) Central India group and at a height of over 1,000 feet above sea-level. As regards regiments, the largest numbers of cases during the year occurred in the Meywar Bhil Corps at Kherwara, the 4th Rajputs at Malakand, the 38th Dogras at Mian Mir, the 52nd Sikhs at Kohat, and the 59th Rifles at Edwardesabad. The disease was much more prevalent but much less fatal among the native troops than among prisoners. Among European troops

pneumonia was more prevalent and fatal, but among prisoners less prevalent and fatal than in the previous year. The medical officers of the 4th Rajputs and 52nd Sikhs consider the extreme cold experienced during December, January, and February, especially on manœuvres, as in part responsible for the prevalence of the disease.

The highest admission-rates for other respiratory diseases during 1905 were recorded in the Northern Command and, among groups, in (XII) Hill Stations, (III) Assam and (VII) North-West Frontier and Indus Valley, the last named being the group from which the highest admission-rate on account of pneumonia was returned. The admission-rate of the whole native army of India on account of other respiratory diseases rose from 21·1 per mille in 1904 to 28·5 per mille in 1905, but the death-rate remained practically the same—·25 per mille in 1904 and ·23 per mille in 1905. Excluding stations where the average strength was less than 100, the highest admission-rates were recorded at Mir Ali Khel (147·8), Fort Jamrud (111·1), Abbottabad (106·1), Thal (96·6), Kherwara (82·4), Ootacamund (75·8), Kirkee (68·1), Bhuj (67·5), Quetta (66·6), Ahmedabad (65·0) and Sehore (63·3); the average strengths of Fort Jamrud, Mir Ali Khel and Bhuj were under 200. Bhuj furnished the high death-rate from other respiratory diseases of 6·13 per mille. Among regiments the 1-6th Gurkhas at Abbottabad, the 64th Pioneers at Ootacamund, the 3rd Sappers and Miners at Kirkee and the 54th Sikhs at Nowshera recorded the highest numbers of admissions during the year. These diseases were most prevalent during the cold months, and, according to the medical officers, were largely due to exposure to cold on field days.

Dysentery and Diarrhœa.—During 1905 the admission and death-rates on account of dysentery were 32·5 and ·18 per mille, respectively, as compared with 31·5 and ·27, respectively, in 1904, the latter rates having been the lowest recorded up to that date. There has thus been a slight increase in the admission-rate, but the death-rate of the year is the lowest on record. Although the admission-rate on account of this disease of the native army as a whole has risen, eight of the twelve geographical groups showed a decrease in prevalence compared with the previous year, the four exceptions being (IV) Bengal-Orissa (the admission-rate being about 35 per mille more than during 1904), (V) Gangetic Plain, (VIII) Central India, and (XII) Hill Stations. The disease was most prevalent during 1905 in (IV) Bengal-Orissa, (I) Burma Coast, (III) Assam, and (VII) North-West Frontier and Indus Valley. Omitting stations with a strength below 100, the highest admission-rates were recorded during the year at Barrackpore (177·5), Aden (157·6), and Fort William (131·1), the first and last named belonging to the (IV) Bengal-Orissa group: the highest death-rates were reported at Kotra (6·67), Kherwara (2·94), and Fort William (1·62). Among regiments dysentery was most prevalent in the 95th Russell's Infantry at Singapore, the 102nd Grenadiers at Mhow, the 8th Rajputs at Lucknow, the 2-10th Gurkhas at Lansdowne, and the 78th Moplah Rifles at Dera Ismail Khan. The medical officer of the 95th Russell's Infantry states that the epidemic in that regiment was caused by the well-water being contaminated. The prevalence of the disease in the 102nd Grenadiers was attributed to the food and water of the men having been unavoidably exposed to dust and sand while on service in the Aden Hinterland.

The admission and death-rates on account of diarrhœa rose from 6·7 and ·05 per mille, respectively, in 1904 to 7·5 and ·06, respectively, in 1905. This disease, like dysentery, was most prevalent in the Eastern Command and, among groups, in (IV) Bengal-Orissa, (III) Assam, and (X) Western Coast. Excluding the smaller stations, the highest admission-rates were recorded at Fort William (93·9), Dibrugarh (37·2), Alipore and Barrackpore, all, except Dibrugarh, which is in Assam, being in Bengal-Orissa. The total number of deaths from this disease among the whole native army was only seven. Several of the medical officers in charge of regiments at the above stations report that the chief causes of the prevalence of diarrhœa were insufficient or improper cooking of food and chills caught while bathing before meals.

Venereal Diseases.—Venereal diseases were nearly eight times more prevalent among the European troops during 1905 than among native troops, the admission-rate being only 19·6 per mille of strength among the latter as compared with an admission-rate of 153·7 per mille of strength among the former; or, otherwise expressed, among European troops an annual average strength of 71,343 gave 10,966 admissions for

venereal diseases, while among native troops an annual average strength of 123,434 gave only 2,419 admissions. The admission-rate in 1905 of the native troops of India, excluding those serving in China and Somaliland, was 1·0 per mille less than in the previous year; the admission-rate of the China Garrison under this heading fell from 43·8 per mille in 1904 to 20·0 per mille in 1905 and that of the Somaliland Field Force from 11·1 in 1904 to 1·9. Altogether 7 men died from, and 79 men were invalided for, these diseases during the year as compared with 6 and 107, respectively, the corresponding figures for 1904. During 1905, venereal diseases were, as usual, least prevalent among native troops located in the Northern Command, but the admission-rate of this Command is five per mille greater, while those of the Western and Eastern Commands are, respectively, four and two per mille less, than in 1904; consequently, the differences in prevalence of these diseases in the three commands are very slight during the year under review. The admission-rate on account of these diseases among Gurkhas in the Northern and Eastern Commands was 34·7 per mille (the same as in 1904); that among native troops of other classes located in these two commands was only 14·5 per mille; that of the whole native army of India, excluding Gurkhas, was 17·6. These figures show that the Gurkhas suffered much more than the sepoys of other classes and that the latter suffer much less in the Northern and Eastern Commands than in other parts of India. Excluding stations at which the average strength of native troops was less than 100, the highest admission-rates for venereal diseases were recorded at Bakloh, Abbottabad and Dharmsala in the Northern Command; at Bhuj, Bombay, and Satara in the Western Command; at Naini Tal, Shillong, and Kohima in the Eastern Command; at Bellary and Vizianagram in the Secunderabad Division; and at Maymyo and Fort Stedman in the Burma Division. Of these stations, Bakloh, Bombay, Satara, Kohima, Vizianagram, Maymyo, and Fort Stedman appeared in the corresponding list in this report for 1904. For native troops in India as a whole, the admission-rate for syphilis was 7·7 per mille, for soft chancre 4·6 per mille, and for gonorrhœa 7·4 per mille, as compared with 8·8, 4·5, and 7·3 per mille, respectively, in 1904.

Beri-beri.—During 1905 beri-beri accounted for only 15 admissions and two deaths against 49 admissions and five deaths in 1904 and 122 admissions and eight deaths in 1903. Of the 15 admissions during the year, ten occurred in two regiments, viz., seven in the 81st Pioneers stationed in the early part of the year at Secunderabad but during the latter part of the year on service in the Aden Hinterland, and three in the 73rd Carnatic Infantry at Aurangabad. The other cases were reported, one each in the 96th Berar Infantry at Secunderabad, in the 20th Deccan Horse at Bolarum, in the 97th Deccan Infantry at Bolarum, in the 63rd Palamcottah Light Infantry at Vizianagram, and in the 88th Carnatic Infantry at Madras. The medical officer of the 81st Pioneers states that all the cases in that regiment were of the wet type except one (that of a man, admitted in the Aden Hinterland, who had twice suffered from the same disease in India), which was of the dry variety. The patients were isolated and the quarters they had occupied disinfected with a view to check the spread of the disease. In 1904 there were six cases of beri-beri in the 81st Pioneers at Secunderabad; and in the same year, the 73rd Carnatic Infantry, which was at that time stationed at Singapore, recorded 29 admissions for this disease.

Guinea-worm.—There was a considerable decrease in the number of admissions for guinea-worm in 1905, the total being 609 against 730 in the previous year. The largest number of cases occurred as usual, in the (VIII) Central India group, the (IX) Deccan, the (XII) Hill Stations, and the (VII) Indus Valley groups coming next. Over 15 per cent. of the total number of cases were reported from Kherwara, where the Mewar Bhil corps is stationed, the number of cases in this regiment during the year amounting to 110, which yields a ratio of 262 per mille of strength. The disease is very common in the native Bhil villages. Excluding Kherwara, cases were most numerous at Poona and Quetta.

Suicide.—During the 10 years, 1895-1904, there were altogether 154 cases of suicide, giving an average of about 15 per annum. In 1905, there were 14 cases, of which nine were by gun-shot, three by hanging, one by drowning, and one by opium-poisoning.

Jails of India.

(For Statistical Tables, *see* pages 138 to 140.)

Sanitary Conditions in 1905.—The importance of prison sanitation in India may be measured by the fact that close upon half a million persons pass through the prisons every year. It is too much to hope perhaps that any considerable proportion of them should profit by lessons of order and cleanliness that they have been taught during their imprisonment; but it is of great importance that none of them should carry away with them from the prison the seeds of disease.

The more closely the problems of jail hygiene are examined, the more evident does it become that the secret of health in the prison is the exclusion of disease from outside, by thorough medical inspection and segregation of newly admitted prisoners, and the limitation of the evil results of any failure of these precautions by making the spread of contagion and the development of latent disease unlikely.

These preventive measures require suitably located, well drained jail sites, properly constructed roomy buildings, the control of the water and food supplies, and efficient management. If these conditions are assured, sickness among convicts should be reduced to a minimum, and the death-rates should be much lower than the death-rates of the free population—the comparison being made not with the crude general death-rates, but with the much lower rates among men and women of the same ages as the prisoners. Prison death-rates, particularly in district jails, depend largely on the health of the prisoners that have to be admitted, but proper appliances, well managed, should banish contagious diseases from the prisons. The proof of the success of jail hygiene is not the low death-rate of a prosperous, healthy year, but the steady growth of the difference between the jail death-rates and the general death-rates in unhealthy years.

In 1904, general conditions were peculiarly favourable to the health of the prisoners; in 1905 conditions in most parts of the country were unfavourable. The weather in the early part of the year was exceptionally cold and raw, the monsoon rains began late and ended early, and the heat of the summer and autumn was excessive. The cold weather crops of 1904-5 were below the average everywhere, except in the Punjab, the Frontier Province, Assam and Burma; and the kharif was bad or below normal in Bengal, Eastern Bengal, and Assam, in parts of Madras, Bombay and the United Provinces, in the unirrigated areas of the Punjab, and in the Frontier Province. Except in Bombay and the Punjab the health of the general population was below the average, and the death-rate, in spite of the great reduction in plague mortality, was higher than in 1904.

The mean daily number of prisoners of all classes in India and the Andamans during 1905 was 106,265, or 1,940 more than in the previous year. The prison populations were slightly lower than in 1904 in the United Provinces, the Punjab, and the Central Provinces, elsewhere they were higher, notably in Burma and Madras, where the mean daily strengths were greater by 935 and 827 respectively.

In the Andamans an addition of 376 to the mean daily strength of 1904 brought the figure of 1905 to 14,348, which is more than a seventh of the Indian daily prison population. It is necessary to treat the statistics regarding convicts in the Andamans separately because the conditions under which they live differ widely from those under which the inmates of prisons in India and Burma live, their sick-rate being nearly three times, and their death-rate twice, as large as the Indian means.

In the jails of India and Burma the mean daily strength in 1905 was 91,917, and the following are the salient statistical facts of the year 1905 compared with those of 1904 and the years 1901-1904. The population of 1905 was greater by 1,564 than that of the previous year, but less by 4,453 than the four years' mean; the rate of admission to hospital was 647 per thousand, or 29 per thousand less than the rate in 1904, which was the lowest on record, and 138 less than the four years' mean; the number constantly sick was 28 per thousand, identical with the figure of 1904, but four below the four years' average, and the death-rate was 19·23 per thousand, 1·62 higher than the unprecedentedly low rate of 1904, but 2·35 below the

four years' average. The admission-rates in all the various administrations were lower in 1905 than the respective means of the previous four years, but only in Burma, the United Provinces, the Punjab, and the Frontier Province were the admission-rates lower than in 1904. The constantly-sick rates were higher in 1905 than in 1904 in Eastern Bengal and Assam, in Bengal, the Frontier Province, the Central Provinces, and Bombay; and in the first three of those provinces they were higher than the means of the four years 1901-1904. The death-rates of 1905 were lower than those of 1904 in Bombay, Burma, the Punjab and Madras, elsewhere there was an increase, and in Burma, Eastern Bengal and Assam, and in Bengal the death-rates of 1905 were higher than the four years' average. The lowest death-rates were 16·33 per thousand in the Punjab, which, with the exception of the rates, 15·89 and 16·05 recorded in 1896 and 1897, respectively, is the lowest in the history of the province, 15·79 in the Central Provinces, and 15·87 in Madras, where the next lowest rate on record was 16·13 in 1899.

Owing to the transfer of fourteen Bengal districts to the new province of Eastern Bengal and Assam, the province of Bengal lost the central jails of Dacca and Rajshahi, and twelve district jails with a total accommodation for 4,749 prisoners; and by the transfer of Sambalpur from the Central Provinces to Bengal, those Provinces lost and Bengal gained one district jail accommodating 155 prisoners.

The daily average number of convicted prisoners in 1905 was 86,375, among whom the death-rate was 19·23 per thousand, the rates ranging from 32·02 in Eastern Bengal and Assam to 14·62 in the Central Provinces. In the following statement are compared the average daily convict populations of central and district jails, and their admission and death-rates in the several administrations in the years 1901 to 1905 inclusive.

* Excluding in 1905 jails transferred to Eastern Bengal and Assam. † Including in 1905 jails transferred from Bengal.

In India as a whole the convict populations are fairly equally divided between central and district jails, but, while the central jail populations are considerably the larger in Bengal, and much the larger in the Central Provinces, Madras, and Burma in the other administrations the district jail populations are the greater. In India as a whole the admission and death-rates are lower among central than district jail populations, and this is the rule with few exceptions in the several administrations; it is, therefore, important when comparing provincial death-rates to take into account the proportions of the total populations confined in central and district jails. It will be observed that the death-rate in central jails, 18·18 per thousand in 1905, is higher than the rates in both 1903 and 1904, but the death-rate in district jails, 20·39, while higher than that of the preceding year, is lower than those of the other years.

Central and District Jails.—The following table shows the distribution according to length of time spent in prison, with the actual number of deaths, and the death-rates of convicts in the jails in the years 1901 to 1905:—

Years.			1. Strength.		2. Deaths.		3. Ratio per 1,000 of Strength.		
			Not exceeding six months.	Above six months and not exceeding one year.	Above one year and not exceeding two years.	Above two years and not exceeding three years.	Above three years and not exceeding seven years.	Above seven years.	Total.
1901	Central Jails.	Strength	14,368	9,769	9,637	6,690	7,221	3,434	51,119
		Deaths	305	212	269	145	205	81	1,217
		Ratio per 1,000 of strength	21·2	21·7	27·9	21·7	28·4	23·6	23·8
	District Jails.	Strength	26,993	10,547	6,766	2,447	1,784	413	48,950
		Deaths	818	277	180	28	36	8	1,347
		Ratio per 1,000 of strength	30·3	26·3	26·6	11·4	20·2	19·4	27·5
1902	Central Jails.	Strength	12,789	8,961	8,941	6,941	7,332	3,565	48,529
		Deaths	280	188	206	122	220	69	1,085
		Ratio per 1,000 of strength	21·9	21·0	23·0	17·6	30·0	19·4	22·4
	District Jails.	Strength	25,610	10,697	6,623	2,584	1,883	361	47,758
		Deaths	588	278	148	49	38	8	1,109
		Ratio per 1,000 of strength	23·0	26·0	22·3	19·0	20·2	22·2	23·2
1903	Central Jails.	Strength	11,122	7,463	7,970	5,715	6,862	2,486	41,618
		Deaths	181	112	137	91	122	37	680
		Ratio per 1,000 of strength	16·3	15·0	17·2	15·9	17·8	14·9	16·3
	District Jails.	Strength	23,242	9,612	5,314	2,279	1,650	209	42,306
		Deaths	587	205	108	28	37	7	972
		Ratio per 1,000 of strength	25·3	21·3	20·3	12·3	22·4	33·5	22·9
1904	Central Jails.	Strength	11,446	7,605	8,328	5,642	6,749	2,475	42,245
		Deaths	196	132	151	70	140	51	740
		Ratio per 1,000 of strength	17·1	17·4	18·1	12·4	20·7	20·6	17·5
	District Jails.	Strength	23,849	9,567	5,348	2,192	1,872	213	43,041
		Deaths	464	157	90	35	24	2	772
		Ratio per 1,000 of strength	19·5	16·4	16·8	16·0	12·8	9·4	17·9

	District Jails.	Strength	23,285	9,771	5,741	2,315	2,063	236	43,413
		Deaths	477	195	125	29	42	8	876
		Ratio per 1,000 of strength	20·49	19·96	21·77	12·53	20·36	33·90	20·18

It will be observed that even in the central jails a large proportion of the total population have been in confinement for less than one year, and that the death-rates in the central jails among such prisoners are much lower than the rates among them in the district jails; that the death-rates in district jails are highest in the first six months of imprisonment; and that in the central jails the highest rate is invariably recorded among prisoners who have spent between three and seven years in prison.

Causes of Sickness and Mortality.—The chief causes of sickness were intermittent fever (admission-rate 181·7 per thousand), dysentery (81·6), abscesses, ulcers, and boils (71·2), diarrhœa (39·2) and respiratory diseases other than pneumonia (26·4); while the principal causes of death were tubercle of the lungs (death-rate 3·19 per thousand), dysentery (3·01) and pneumonia (2·28).

Intermittent Fever.—There were 16,704 prisoners admitted to hospital on account of intermittent fever, or 2,821 fewer than in 1904, and little more than half the number admitted from the somewhat larger population (105,020) in 1901. This disease was, as usual, most prevalent in October, and the admission-rates were

highest in the North-West Frontier Province (344·0 per thousand), and Bengal (290·7), the rates ranging in the other provinces from 260·1 per thousand in Eastern Bengal and Assam, to 85·6 in Madras and 51·0 in Burma. The mean death-rate ascribed to intermittent fever was ·91 per thousand. In the Central Provinces and North-West Frontier Province no death was recorded; in Bengal and Eastern Bengal and Assam the death-rates were 2·75 and 1·87 per thousand, respectively, and in the remaining provinces the rates varied between ·79 in Madras and ·13 in Bombay.

Remittent Fever.—There has been a great reduction during the last five years in the numbers of cases and deaths returned under the designation remittent fever; but in contrast to the gradual reduction in the numbers of cases of intermittent fever, the fall in the numbers of cases of remittent fever has been abrupt. In 1901 there were in all the jails 295 admissions and 41 deaths ascribed to this disease, and in the following year the number of admissions rose to 346, and there were 40 deaths; in 1903 the number of admissions and deaths fell to 143 and 19 respectively; in 1904 the figures were 102 and 15, and in 1905 the number of admissions increased by 7 to 109, and the number of deaths by 5 to 20.

During the quinquennium ending with 1905, there were in all 995 cases of remittent fever, of which 647 occurred in three provinces, Bombay (314), Bengal (174), and Burma (159); and in the different provinces the case-mortality varied greatly between 29·6 per cent. in the Punjab and 5·3 per cent. in the Central Provinces. The vast majority of the cases—875 out of 905—occurred in district jails and the case-mortality among them was 12·5 per cent., as compared with 21·7 per cent. among the 120 cases reported from central jails. In 1905 the largest numbers of cases occurred in Bengal (21), the United Provinces (21), and Madras (19); but while in the United Provinces the largest number of cases in any one jail was five, in Bengal there were 13 cases in the district jail at Champaran, and in Madras there were 12 cases in the district jail at Tanjore.

As usual, the disease was least prevalent in the cold weather, but in no other respect does its incidence agree with that of intermittent fever. The reports on fatal cases do not generally throw a clear light upon the nature of the disease, although in many instances the disease does not seem to have been malarial. We have, then, a disease more frequent in some provinces than in others, less fatal, but more frequent in district than in central jails, the incidence of which, in the course of a single year, declined by half; the question arises, what is its nature? Many cases are no doubt severe attacks of malarial fever, others are *kala azar*, and others again are confessions of failure to diagnose. Our knowledge of the nature of Indian fevers becomes wider and more exact every year, but it is still far from complete, and it is just these obscure cases of fever which are likely to give an opportunity to the pathologist to enlarge our knowledge.

Quinine prophylaxis is in general use, and so also, apparently, are measures to prevent the breeding of mosquitoes in jails. Little mention is made by Inspectors-General of special measures undertaken in the jails, or of the results obtained by them, and this omission is perhaps justified by the familiarity of the subject, and by the great reduction of malaria among prisoners in recent years. The very fact of success should, however, encourage us to redoubled efforts, for a great deal can still be done. Making every allowance for the varying prevalence of malaria in different localities and in different years, the mean admission-rate represents extraordinary variations in the different administrations, and in the different jails under them. There were in 1905 seven jails with a mean daily strength of over 100 prisoners, in which the admission-rate for intermittent fever was over 600 per thousand—to take a figure more than three times as great as the mean—and in some of these the frequency of malarial fevers does not appear to have attracted the special notice of the Medical Superintendent. The explanation in some cases, no doubt, is the fact that in other respects the prisoners were very healthy with low death-rates, and in others the difficulty of draining of the jail and its surroundings is considered insuperable from want of funds. It is, however, wiser in the long run to spend money on drainage than on hospital charges, to which has to be added the loss of labour; and in most cases the reports appear to warrant the hope that well devised efforts intelligently directed and persistently carried out would be successful.

Dysentery.—The total number of recorded cases of dysentery in 1905 was 7,496, equal to an admission-rate of 81·6 per thousand, which is considerably lower than the rate in the previous year (85·7), and the mean of the previous four years (89·9).

The number of deaths was 277, equal to a death-rate of 3·01 per thousand, which, while slightly higher than the exceptional rate (2·91) of 1904, is considerably lower than the four years' average (3·87). As compared with 1904 there was a diminution in the number of cases in all administrations except Eastern Bengal and Assam and Madras, the decrease being specially remarkable in Burma, where the number fell from 561 to 358, and in the Punjab, where it fell from 570 to 327. In India generally the disease was most prevalent in August and least prevalent in February, the important provincial exceptions being the United Provinces and the Punjab, in both of which the maximum occurred in September, and Madras, where it occurred in October. The dysentery death-rates in 1905 were higher than in 1904 in all provinces except Bombay, where the rate remained stationary, Burma, where the reduction was ·21 per mille, the United Provinces, where the fall was ·40 per mille, and the Punjab, where the death-rate decreased from 2·56 to ·52 per thousand. The case-mortality varied greatly, ranging from 10·0 per cent. in the North-West Frontier Province to 1·8 per cent. in the Punjab, the mean for India being 3·7, and the percentages in all provinces except the North-West Frontier Province, Burma (9·2), United Provinces (5·3), and Madras (4·8) being below the mean.

It is a misfortune when a disease is given a pseudo-scientific name from a symptom, for, unless this symptom is peculiar to one disease, a serious obstacle is placed in the way of the discovery of its etiology, and when this is discovered, there is confusion regarding the assignment of the name.

Dysentery affords a striking example of the truth of this statement. The symptom from which the name is taken is common to several diseases, it has taken a comparatively long time to discover their etiology, and great confusion prevails regarding their causes. Our knowledge has, however, advanced rapidly in recent years, and the problem is so nearly solved that it is perhaps possible to classify the diseases with some approach to correctness. We may divide dysenteries into three classes: (*a*) epidemic or bacillary dysentery, caused by one or other type of the dysentery bacillus; (*b*) tropical, endemic or amœbic dysentery caused by the *Entamœba histolytica* of Schaudinn; and (*c*) false dysentery, including diseases characterised by discharges with more or less dysenteria, caused by inflammation of the bowel from any other cause, *e.g.*, bacteria, *Entamœba coli* and *Balantidium coli*.

As bacillary dysentery is not necessarily epidemic, and may be endemic, and as amœbic dysentery occurs outside the tropics in places where it is not endemic, it is desirable to avoid alternative names, and adhere to the terms bacillary dysentery and amœbic dysentery.

There are at least two well-known types of the bacillus of dysentery—the Shiga-Kruse and the Flexner. On the one hand, however, authorities are agreed that these are not specifically distinct germs, but rather races of the same germ displaying biological differences; on the other, observers by the discovery of minor differences in the fermentation and agglutination reactions of the bacilli of various epidemics are adding to the number of types, thus Hiss describes four types, and Shiga, writing of the dysenteries of Japan, five.

It is probable that there is no need to depart from a conception of the specific unity of the bacilli of dysentery, and that the importance of para-dysenteric bacilli may be limited to the preparation of vaccines or sera which may have to be polyvalent. Shiga states that the bacilli persist for a long time in the intestines of convalescents, and may be carried by the apparently healthy, and Conradi has found dysentery bacilli in the stools of healthy persons in Metz. The life of the bacilli outside the body is, according to Shiga, of short duration. Frost and Whitman found that at 17°—20° C., while the bacilli exposed on dry wood or paper died out rapidly, they lived for days and even for a month on dry bread or rice; and that although they seldom lived for a week in distilled water, they lived in milk until it dried up. The Shiga type was less hardy than the Flexner type, and the higher the temperature the sooner the bacilli died. Observations connecting the severe summer diarrhœas of children with the bacilli of dysentery are accumulating; according to Jehle and Charleton the Shiga-Kruse type is most common in epidemic diarrhœa, and the Flexner type is most common in sporadic cases. The connection of diarrhœa in children with dysentery has an obvious application to the prevention of the disease, while the rôle played by flies in the contamination of food as described by Sandilands not only demonstrates the necessity for the immediate destruction of dysenteric dejecta, but suggests other means of precaution, such as the suitable location of dysentery wards and latrines.

It is important that the cause of each case of dysentery should be ascertained. Leaving the clinical signs and symptoms on one side, we have the following means of diagnosis: (1) serum diagnosis—the bacillus of dysentery is agglutinated only by the blood of the subjects of bacillary dysentery, but the agglutinating property does not appear in the blood until about the end of the first week; (2) the recovery of the bacillus by cultivation from the fæces; and (3) the discovery of amœbæ in the stools. In fresh material from an acute case of dysentery, under a low power, the amœbæ appear as small, clear, shining discs; higher magnification revealing active movements. They may be distinguished from large leucocytes by their greater size (10—30 μ Kartulis) by the greater development of pseudopodia, and by more lively movements; and from the *Entamœba coli* by the generally distinct division of the clear ectoplasm from the granular endoplasm, which in the *Entamœba coli* are distinct only when it is moving actively, by the small, generally eccentric nucleus, by the absence of a nuclear membrance, and by the formation of small cysts (3—6 μ) which according to Lesage, can be readily seen a few minutes after the addition of iodised water. Difficulty in seeing the amœba may arise from absence of movement which may be due to too low temperature of the slide or the presence in the stool of an antiseptic drug, *e.g.*, calomel (Kartulis).

It is probable that the *Entamœba histolytica* is not the only pathogenic amœba, and although Kartulis states that all dysenteric amœbæ examined by him have been the same, he says that Schaudinn informed him that he recognised two varieties, and that Ruge believes the dysenteric amœbæ of China differ from those found in Java. Numerous cultivation experiments have been made with amœbæ, and Lesage describes the successful cultivation of *Entamœba histolytica* in association with a bacterium of the coli group on washed, sterilized agar. The same observer states that the resistance of the living amœbæ in culture is remarkable, the amœbæ living for four to five months, and the cysts for six to eight months at a temperature of 20°—25° C. As pointed out by Schaudinn the cysts are the more dangerous form, probably because they are more resistant to the gastric juice, and cysts are formed in the intestine at the termination of a case, and, outside the body, whenever, apparently, conditions are unfavourable to the life of the amœba; cold, for instance, will cause amœbæ to form cysts.

Infection may persist for very long, even after the patient is apparently quite cured, a refuge of the amœbæ being the vermiform appendix. Of especial interest is the fact that these amœbæ may be the cause of intractable chronic diarrhœa. Meyer cites two cases where the diarrhœa had been of 15 years' duration, and a third of 18 years' duration, in which cure followed specific treatment administered on the discovery of the presence of amœbæ in the stools.

In the Andamans, Major Anderson, I.M.S., reports that the *Entamœba histolytica* was found in 488 of 920 cases of dysentery examined, but in only 29 of these cases were the amœbæ unaccompanied by other protozoa. In order to check these figures an examination was made of the dejecta of 118 men admitted to hospital for fever, of whom 34 had suffered from dysentery more than a year previously, and 84 had never been admitted to hospital for dysentery. Among the 34 the amœba was found in 15; among the 84 amœbæ were present in 17; in a few instances these amœbæ resembled those found in the dysenteric cases, but in most instances the amœbæ conformed with the description of *Entamœba coli*.

In view of the connection established between dysentery and abscess of the liver, the proportions between the numbers of these diseases occurring among prisoners and others is interesting. In the Andamans in 1905 there were 2,359 cases of dysentery admitted into hospital—perhaps we may assume that 1,000 were cases of amœbic dysentery—and three cases of abscess of the liver; in the last five years there have been 10,428 cases of dysentery and 11 cases of abscess of the liver. In the Indian jails in the last five years there have been 42,152 cases of dysentery and 42 cases of abscess of the liver. In the Native Army the proportion was much higher, 23,516 cases of dysentery and 72 cases of abscess of the liver. The contrast between these figures and those for the European Army is an extraordinary one; among British soldiers, during the five years there were 5,581 cases of dysentery and 860 cases of abscess of the liver. It is evident then that although dysentery may be a necessary antecedent of abscess of the liver, abscess of the liver is not among natives a common sequel of dysentery; and it appears that there must be some other condition operative among Europeans. Musgrave notes that experiments in his laboratory indicate that amœbic abscess rarely or never develops in

an otherwise normal liver, notwithstanding the fact that amœbæ may be almost constantly poured into it from an ulcerated bowel. Allusion may be made to the report of an isolated experiment in which Dr. Gauducheau injected pus from a tropical abscess into the mesenteric vein of a dog; the result was not an abscess of the liver, but amœbic dysentery.

Diarrhœa.—The number of cases admitted to hospital under this heading was 3,603, of which 68 ended fatally, the mean admission and death-rates being, respectively, 39·2 and ·74 per thousand, the lowest on record. The highest admission-rates were 90·9 per thousand in Bengal and 90·0 in Eastern Bengal and Assam; in the other administrations with one exception, the rates varied between 42·9 in the Punjab and 17·6 in Burma; the exception is Madras, where the admission-rate was 3·5 per thousand and only 36 cases were recorded as diarrhœa. The highest death-rates were 1·15 per thousand in Bombay and 1·06 in Bengal, the rates in Madras, ·30, the Central Provinces, ·28, and the Punjab, ·17, being the lowest.

Respiratory diseases, other than pneumonia.—The number of cases admitted on account of diseases classified under this heading was 2,428, and the number of deaths was 85, the rates being 26·4 per thousand and ·92 per thousand as compared with 25·1 and ·65 in 1904. The increase in the admission-rates which depended to some extent on the greater prevalence of influenza was common to all administrations, except the North-West Frontier Province, the Central Provinces and Madras, and the increase in the death-rates was common to all except the North-West Frontier Province and Madras.

Pneumonia.—In spite of the wide diffusion of influenza the number of cases of pneumonia fell from 965 in 1904 to 896 in 1905, and the number of deaths from 252 to 210, the admission and death-rates, 9·7 and 2·28 per thousand, respectively, being the lowest on record. The reduction in the admission-rates was most remarkable in the Punjab and the North-West Frontier Province; in Burma, Madras, the United Provinces and the Central Provinces the admission-rates rose. The death-rate fell in Eastern Bengal and Assam, the Punjab, the North-West Frontier Province and Bombay, the further reduction from 19·34 per thousand to 15·79 in the Sind Gang in that province being satisfactory. The case-mortality varied considerably in the different provinces being exceptionally high in Bengal (34·1 per cent.), Burma (31·0), Eastern Bengal and Assam (28·1), and comparatively low in the Punjab (17·7), Madras (16·7), the Central Provinces (14·3), and the North-West Frontier Province (11·1). The mean stay in hospital of fatal cases was between eleven and twelve days; in the United Provinces and Bombay the mean duration of fatal cases was only about seven days owing to the large numbers of cases which proved fatal in the first few days of the disease.

The importance of efficient ventilation in the prophylaxis of pneumonia is recognised everywhere, and endeavours are generally used to secure the best ventilation of the sleeping wards possible; but it is obvious that the difficulty of this task may be greatly increased by climatic conditions and badly constructed buildings. When cases occur in the prisons those measures of segregation and disinfection considered necessary in other cases of infectious fevers are general carried out. Attention has recently been drawn to the possible rôle played by oral sepsis in predisposing to the more serious prison diseases, and in this connection the recently made statement that the pneumococcus, which is present in the mouths of a certain proportion of healthy persons, increases in virulence in a neglected mouth and disappears altogether from a thoroughly cleansed one, may be noted.

Tubercle of the lungs.—As compared with the previous year there was a considerable increase in the prevalence and fatality of cases of tubercle of the lungs, the number of admissions rising from 763 to 803, and the number of deaths from 279 to 293—an admission-rate of 8·7 per thousand and a death-rate of 3·19. The disease was as usual most prevalent in the jails of Bengal (admission-rate 13·5 per thousand), Eastern Bengal and Assam (11·4) and Madras (10·5), and least prevalent in the jails of Bombay (6·1), the Central Provinces (5·6) and the North-West Frontier Province (3·8); while the death-rates were highest in Bengal (4·02 per thousand) and the Punjab (4·43), and lowest in the Central Provinces (1·97) and the North-West Frontier Province (1·52).

In India generally, tubercle of the lungs was the cause of 16·6 in every hundred deaths. This percentage varied greatly in the different administrations, the more remarkable percentages being 27·1 in the Punjab, 22·3 in Burma, 12·5 in the Central Provinces, 10·4 in Eastern Bengal and Assam, and 7·7 in the North-West Frontier Province. In India generally, and in Burma, the United Provinces, the Punjab, Bombay and the Central Provinces, tubercle of the lungs was a more frequent cause of death among prisoners than dysentery. Analysis of the statistics shows that the mortality from tubercle of the lungs was much higher among those convicts who had been more than three years in prison than among the remaining body of convicts, the death-rates being 8·06 among the former and 2·59 among the latter. Unfortunately the returns giving the numbers admitted to hospital do not discriminate between short and long term prisoners, and the death-rates alone cannot give accurate information regarding the prevalence of the disease among short and long term prisoners, respectively, because a larger number of the former than of the latter are likely to be released before the termination of the disease. Of the 90 long term prisoners that died, however, 47 were in good health at the time of conviction, and the mean duration of their illness from admission to hospital until death was 124 days, so that it is reasonable to suppose that the great majority contracted the disease in prison. There are considerable differences in the mean stay in hospital of these cases in the different administrations; in Bombay the mean was only 68 days, in Madras 83 and in the Central Provinces 84, while in the United Provinces the number of days spent in hospital was 153, and in Bengal 142.

The nature of tubercular infection and the manner of the entry of infection into the human body are still the subjects of a discussion to which allusion is made only for the purpose of directing attention to the possibility of a proportion of cases of tubercle in the jails being the development of a latent infection. That this is possible is suggested by the large number of cases which occur among apparently healthy prisoners in jails where the hygienic precautions taken might be expected to exclude the probability of infection; and the possibility emphasizes the importance of a strict watch over the health of those prisoners whose physical conformation or previous history indicates the possible presence of latent tubercle.

The principles of prevention as recently described by Koch in the Nobel lecture are thoroughly understood in the jails, and are generally applied. In many prisons tuberculous patients are treated in a special open-air ward, but these wards are not all equally well constructed. Care should be taken that, while the occupants of the ward are not exposed to chilling winds, ventilation is thorough, and that there is no dead space in the roof in which the air can stagnate; the existence of such a dead space will render the air of a ward, even if it be completely open on all sides, unpleasant in still weather. The arrangements for the reception and disposal of tuberculous sputum should be complete and the ward should be kept scrupulously clean, otherwise it may become a centre for the collection and distribution of tuberculous material.

Anæmia and Debility.—There were 1,014 cases and 50 deaths recorded under this heading, with admission and death-rates of 11·0 and ·54 per thousand, respectively, as compared with 12·4 and ·41 in the previous year and means of 13·5 and ·57 in the previous four years. These conditions of bad health were far more prevalent in the jails of Eastern Bengal and Assam than in that of any other administration, the admission-rate being 32·2, and the death-rate 2·66 per thousand, compared with 17·9, the next highest admission-rate, recorded in the Punjab, and ·76 the next highest death-rate, recorded in Bombay. The lowest admission-rates were 4·3 in Madras and 3·1 in Burma, and in all provinces the admission and death-rates were below the means of the last four years except in Eastern Bengal and Assam where both rates were higher, Bengal and the North-West Frontier Province where admission-rates were higher, and the Punjab where the death-rate was higher. The geographical distribution of the high death-rates is important; they were highest in Assam (Group III.) 5·75, Western Coast (X.) 1·73 and Bengal and Orissa (IV.) ·92. The convenience of the heading anæmia and debility for the purpose of hospital registers is obvious, but the condition must depend upon some cause either in the victim or his surroundings, and the occurrence of large numbers of such cases in a jail should lead an Inspector-General to ascertain whether they are due to failure to diagnose or to some remediable defect in the conditions of the prisoners' lives. The *post-mortem* records show easily recognizable organic disease in many cases; a few cases were almost certainly *kala azar;* and anchylostomes

were frequently found in the intestines. In this connection attention may be drawn to the revival in a modern form by Shipley and Fearnsides of the old idea that the anæmia of anchylostomiasis is due to a hæmolytic toxin secreted by the anchylostomes —probably in the cephalic glands.

Small-pox.—There were in all 31 cases of small-pox, including 14 in Bombay and four each in Madras and the United Provinces, as compared with 25 cases and four deaths in 1904.

Plague.—There were 66 cases of plague in the jails, of which 46 were fatal, as compared with 37 cases and 24 deaths in 1904. In the United Provinces (26 cases) the disease appeared in eleven jails; in Bombay (15 cases) in four jails; in Bengal (14 cases) in six jails; in the Punjab (6 cases) in three jails; in the Central Provinces (3 cases) in two jails; in Burma and Ajmer one case each.

Cerebro-spinal Fever.—The decrease in the numbers of cases of this disease was maintained, the number of cases and deaths falling from 23 and 18 in 1904 to 10 and 9 in 1905, and the number of jails in which cases occurred from eleven to six.

Enteric Fever.—There were 64 cases of enteric fever and 15 deaths, a larger number of cases than in any of the past ten years except 1902, when there were 69 cases and 15 deaths. There were 28 cases in the Madras jails, Coimbatore contributing 18 and Cannanore six. In Eastern Bengal and Assam there were 12 cases, ten in the Mymensingh jail and two at Rangpur. No case was reported in Bombay, the Central Provinces or the North-West Frontier Province. In most instances the *post-mortem* observations supported the diagnosis.

Cholera.—The number of cases of cholera was 73, of which 40 were fatal against 47 and 31 in 1904, and 97 and 57 in 1903. Most of the cases (37 with 14 deaths) occurred in Madras, an outbreak in the jail at Rajamundry accounting for 30 cases of which ten were fatal. In Eastern Bengal and Assam there were twelve cases and all were fatal. Except at Rajamundry the cases were sporadic, and the jails in Bombay and the North-West Frontier Province were free from the disease.

The following paragraphs deal with the more important features of the provincial reports.

Bengal.—The year was comparatively unhealthy; there was a slight increase in the mean daily population and the admission and death-rates rose from 883 and 19·55 per thousand in 1904 to 954 and 24·91. The difficulty in providing sufficient accommodation has been increased owing to the more complete separation of different classes of prisoners that is now required; and it is evident that steps must be taken to obtain more accommodation, since in 16 jails there was overcrowding among convicts throughout the year and in nine jails the under-trial wards were not sufficiently large for the number of under-trial prisoners in confinement. The principal causes of admission to hospital were intermittent fever (30·49 per cent. of all admissions) and dysentery and diarrhœa (30·12); and the principal causes of death were dysentery (26·3 per cent. of all deaths), tubercle of the lungs (16·1), intermittent fever (11·0), and pneumonia (8·5). There were 2,783 admissions to hospital on account of dysentery and 93 deaths, a case-mortality of 3·34 per cent., which is below the mean for Indian jails (3·7), and may be due, as the Inspector-General suggests, to prompt admission to hospital of mild cases, or to the presence of a less deadly form of the disease. Regarding oral sepsis the Inspector-General remarks that medical officers have not been able to trace any connection between it and the prevalence of dysentery, and they do not consider the condition in any sense scorbutic. Even if there is no direct connection between oral sepsis and dysentery it cannot, as the Inspector-General says, be good to swallow pus organisms; the loss of teeth must result in dyspepsia which is generally considered a predisposing cause of dysentery; we have seen that the presence of oral sepsis may determine an attack of pneumonia, and there is evidence that it may furnish an entrance for tubercular infection in the young; the removal of the condition, therefore, is an important detail of jail hygiene.

There was a slight reduction in the number of cases of intermittent fever, the total being 4,120, compared with 4,271, in the preceding year, but the number of fatal cases rose from 12 to 39. Nearly half the deaths occurred in cases of malarial cachexia and it seems possible that some of these were cases of *kala azar*. Quinine prophylaxis is used by Koch's method, and the Inspector-General remarks that the result is not seen in any considerable reduction in the number of admissions for

fever, but most medical officers comment on the fact that the disease is of a milder type and more easily cured. Tubercle of the lungs was more prevalent and fatal than in the previous year, and the Inspector-General proposes to segregate at Berhampore tubercle cases from all jails.

The death-rate in four jails was over 40 per thousand; one of them, Khulna, is a small jail and the death-rate must vary. The high death-rate in the others is attributed to overcrowding or to structural defects in the barracks.

Eastern Bengal and Assam.—There was a slight increase in the average strength—from 6,211 in 1904 to 6,401 in 1905—of the prisoners in the jails of Eastern Bengal and Assam. The year was unhealthy, the admission, constantly-sick and death rates rising from 979, 37 and 22·38 per thousand, respectively, in 1904, to 1,081, 46, and 32·96 in 1905, rates which are higher than those recorded in recent years. The chief causes of sickness were dysentery and intermittent fever, and, to a less extent, diarrhœa. The deaths were due to dysentery, tubercle of the lungs and beri-beri which occurred in an epidemic form at Sylhet and caused 21 deaths. In five of the jails, with a population of over one hundred, the death-rates exceeded 45 per thousand, namely, Barisal (62·87), Gauhati (58·25), Dibrugarh (57·69), Sylhet (54·79), and Tezpur (45·28).

United Provinces.—Climatic conditions were not favourable to the health of prisoners: the cold in the early months of the year was extreme, and the hot weather was more trying than usual. There was considerable distress among the agricultural population; and influenza was prevalent. In these circumstances it is satisfactory to note a considerable reduction in the admission-rate from 612 per thousand in 1904 to 569 in 1905, and a fall in the constantly-sick-rate from 28 to 27. The death-rate, however, rose from 14·56 of the previous year, which was the lowest ever recorded, to 17·31; this is not a high rate and the Inspector-General remarks that at least a third of the deaths were due to diseases contracted before admission to jail or to injuries. The increase in mortality was due to heat apoplexy and the occurrence in the jails of a large number of cases of plague.

The chief cause of sickness was intermittent fever (32 per cent. of all admissions); and the chief causes of death were pneumonia (17·3 per cent.), tubercle of the lungs (15·4) and dysentery (11·2). In seven jails with a strength of over 100 prisoners including the central jail at Benares the death-rates were over 30 per thousand. The high death-rate in the Benares central jail (33·6) is of particular interest as the situation, arrangement and management of the jail are satisfactory, and the death-rate of 1904 was only 10·37. The population of the jail had been reduced and it contained a very large proportion of old men whose latent organic defects rendered them unable to withstand the peculiarly unhealthy conditions prevalent in the Benares district. At Gorakhpur the special precautions taken for the purpose of preventing dysentery getting into the jail, to which reference was made last year, were successful and only one death from dysentery occurred in the jail.

Punjab.—The daily average population has been steadily falling since 1900, and in 1905 the daily average convict population was lower than it has been since 1896.

The year 1905 is a memorable one in the annals of the Punjab jail administration: the admission-rate fell from 907 per thousand in 1904 to 708, the constantly-sick-rate from 31 to 26, and the death-rate from 19·76 to 16·33—one of the two lowest rates on record. Very remarkable was the decline in the numbers of deaths from dysentery from 30 to 6, and from pneumonia from 64 to 29. The number of deaths from tubercle, however, rose from 40 to 51 and there were 13 deaths from sunstroke, four from cholera and five from plague. The number of admissions to hospital on account of malarial fever fell from 4,014 to 2,834, and the number of deaths from 10 to 6, which is attributed to "the administration of quinine in large doses at stated intervals during the malarial season and especially to prisoners after admission, together with the abolition of breeding-grounds of mosquitoes in the vicinity of jails."

Colonel Bate, C.I.E., I.M.S., who had held the office of Inspector-General of Prisons in the Punjab since April, 1891, demitted office on promotion. The improvements in the condition of the prisoners effected by him during his long

tenure of office may be judged from the following figures: in the ten years ending 1891 the mean death-rate was 32·77, in the following ten years the mean death-rate was 22·14, and in the four years ending 1905 it was 20·19.

North-West Frontier Province.—The daily average population was 1,314, showing a continuation in the steady increase due to heavier sentences and fewer transfers to the Punjab jails. There was occasional overcrowding especially in the Kohat and Abbottabad jails. The admission-rate fell from 1,102 per thousand in 1904 to 960, but the constantly-sick and death-rates rose from 32 and 14·65, respectively, to 34 and 19·79. The principal causes of sickness were ague, abscesses and influenza, and dysentery was the chief cause of death.

Central Provinces and Berar.—The average daily population fell from 3,740 in 1904 to 3,547 in 1905; but the admission, constantly-sick and death-rates all rose—from 586 to 630, from 20 to 21 and from 12·57 to 15·79. The number of admissions on account of malarial fever was greater than in 1904, and this fever accounted for 30·27 per cent. of all admissions, but there was no fatal case. Tubercle of the lungs, pneumonia, other respiratory diseases and dysentery were the principal causes of death. The number of cases of pneumonia increased from 25 to 35, and it was suspected that infection was conveyed by blankets, which are to be systematically boiled in future. In the five central jails there were only 81 admissions and three deaths from dysentery, and it is noteworthy that in the Jubbulpore central jail, which was recently notorious for the high mortality from dysentery in it, a daily average population of 840 was entirely free from that disease throughout the year. The number of cases of diarrhœa fell from 169 to 128, but the Inspector-General considers that the number should be still lower, and alludes to the practice of habitual convicts securing a holiday in hospital on account of diarrhœa induced by eating irritant seeds.

Madras.—There was a considerable increase in the daily average strength from 9,320 in 1904 to 10,147. The admission-rate rose from 439 to 469, but the constantly-sick and death-rates fell from 20 and 16·52 per thousand to 19 and 15·87, both lower than any hitherto recorded. The death-rate would have been only 14·49 but for the occurrence of cholera of which there was an epidemic (30 cases, but only ten deaths) at the Rajamundry central jail and (seven cases with four deaths) in the Madras Penitentiary and Nellore district jail. Ague (18·25 per cent. of all admissions), dysentery (13·63 per cent.), simple continued fever (7·24 per cent.) were the chief causes of sickness; dysentery (19·3 per cent. of all deaths), tubercle of the lungs (14·9 per cent.), pneumonia (9·3 per cent.) and cholera (8·7 per cent.) were the chief causes of death. The special hospital for tubercle at Trichinopoly was in use with much advantage throughout the year; the construction of the special hospital at Bellary has not been completed.

Bombay.—The daily average population increased slightly to 7,851, and the admission and constantly-sick-rates rose from 600 to 603, and from 25 to 27 per thousand, respectively, but the death-rate fell from 19·22 to 17·45, the lowest rate recorded.

The principal cause of sickness was ague which accounted for 22·30 per cent. of all admissions. The chief causes of death were pneumonia (17·5 per cent. of all deaths) and tubercle of the lungs (13·1 per cent.). There was overcrowding in the Common Prison, Bombay, Rajkot, Hyderabad, and Shikarpur. The Thana jail was overcrowded for a short time, but during the greater part of the year the population was kept below the number for which accommodation is provided according to scale. The death-rate of this jail fell from 23·39 in 1904 to 14·83 and although tubercle continues to be the principal cause of mortality, the measures taken—the provision of a tubercle ward, early isolation of cases, the renewal of every floor in the prison and the thorough disinfection of the floors—have brought about a great diminution in the prevalence of the disease.

The total number of cases of pneumonia fell from 119 to 106 and the number of deaths from 38 to 24. In the Sind Gang there was no virulent outbreak and the Inspector-General quotes Major Jackson's opinion that the improvements effected in the surroundings of these prisoners will render pneumonia no longer formidable among them.

Burma.—There was a considerable increase in the daily average strength from 11,704 in 1904 to 12,639 in 1905, a number not far short of the total, 15,284 for which accommodation is provided. The health of the prison population continued excellent, the admission and constantly-sick-rates falling from 387 and 20 per thousand to 320 and 17—the lowest rates on record—and the death-rate from 18·63 to 17·01, the third lowest rate on record. The food of the prisoners was the subject of particular attention during the year, and arrangements were made to secure pure drinking water for the inmates of the jail at Mandalay. The success which has attended the efforts to improve the hygiene of this jail may be gauged from the reduction in the death-rate from 79·30 per thousand in 1904, to 17·31. The jail at Thayetmyo, however, was unhealthy in 1905, the death-rate rising from 12·91 in the previous year to 37·66, due to the prevalence of dysentery and diarrhœa for which the flooding of the jail's surroundings owing to an unusual rise of the river and the pollution of the river water are blamed. There were seven cases of beri-beri and four deaths in this jail in which, it may be noted, a great outbreak of that disease occurred in the summer and autumn of 1881. The recent outbreak was promptly checked by the removal of the patients from the jail and the disinfection of their clothing and bedding and of the dormitories occupied by them. The chief causes of sickness were abscesses and ague and the chief causes of death were tubercle of the lungs and dysentery. The term "abscess" includes the results of injuries, many of which were found to be self-inflicted.

Ajmer, Mercara, Quetta and Secunderabad.—In the jail at Ajmer there was some overcrowding, but the health of the prisoners was remarkably good, the constantly-sick and death-rates among a population of 412 being 22 and 17 per thousand, respectively. Prisoners often suffer from guinea-worm attributed to the drinking water. There was one death from plague. In the Mercara jail the average daily population was 87, and the constantly-sick and death-rates 11 and 45·98 per thousand, respectively. The general health was good; of the four deaths, three were due to pneumonia. At Quetta the average daily population was 70; there was no death. At Secunderabad the average daily population was 85; there was no death.

Andamans.—In 1905 the rainfall recorded in the Andaman Islands was 101·09 inches, which is twenty inches less than the fall of the preceding year and about seventeen inches below the mean of the preceding five years. The convict population continues to increase, the average daily strength rising from 13,972 in 1904 to 14,348. No change has been effected in the permanent barracks, but many bamboo and thatch barracks were constructed and occupied during the year, while two additional wards for phthisical patients and an additional ward for lunatics were opened, one of the former being used for general hospital purposes. No change has been made in the water-supply or in the conservancy arrangements. The swamp to the north of the female jail was partially drained, but still includes pools in which anopheles mosquitoes breed. No change was made in the diet scale, but the quality of the supplies has been improved. The Senior Medical Officer considers that the inferior quality of the wheat, particularly its mouldiness, is a principal cause of the dysentery which is so prevalent among the convicts and the results of a series of experiments carried out with wheat cleaned and ground by different methods afford evidence of the correctness of his view. He recommends that in future (1) all foreign matter and diseased grain should be carefully removed from the wheat before grinding; (2) the wheat and *atta* should be systematically dried; (3) excess of bran should be removed from the *atta* after grinding; (4) each sack of food material should be carefully inspected before issue for use; and (5) the food should be stored in a godown rendered as far as possible damp proof and weevil proof. The use of several kinds of *dhal* has been introduced. The vegetables issued to the convicts have been of much better quality owing to the increased number of gardens in various stations, with the result that scurvy is rarely seen. Cleaned vegetables are now issued to the inmates of the female and cellular jail. Improvements have been effected in the milk supply.

The admission-rate fell from 1,909 per thousand in the previous year to 1,898, but the constantly-sick and death-rates rose from 64 and 34·75 per thousand to 68 and 38·96. The increases in the constantly-sick and death-rates were due to the prevalence of dysentery and cellulitis in the first part of the year; and the

constantly-sick-rate is kept up by the detention in hospital of all recognized cases of phthisis.

Dysentery is the great scourge of the Settlement; the number of cases in 1905 was 2,359 or 89 more than in the previous year, and the number of deaths rose from 111 to 187, equal to a death-rate of 13·03 per thousand, four times the Indian mean death-rate. The admission and death-rates from tubercle of the lungs were 11·4 and 6·48 per thousand; both rates lower than those of the preceding year, and this encourages the hope that the vigorous measures adopted against the disease are successful. The average stay in hospital of fatal cases was 230 days.

Malaria was the cause of 17,881 admissions and 12 deaths, compared with 16,395 admissions and 34 deaths in 1904. The most common anopheles found in the Settlement resembles *A. rossi*, but Lieutenant-Colonel Alcock, I.M.S., considers it differs sufficiently to deserve another name and has provisionally named it *A. andersonii*. This mosquito and *A. barbirostris* are considered by Major Anderson, the Senior Medical Officer, to be the common carriers of malaria. Cellulitis which caused 188 admissions and 18 deaths was, as already noted, most prevalent early in the year, but became much less virulent as the year advanced; the improvement being attributed by the Senior Medical Officer to improved barrack accommodation.

Conclusion.—The general results of jail management during the year, so far as the health of the prisoners is concerned, were satisfactory, and the Government of India have good reason to be well pleased with the care and skill displayed by the Inspectors-General and the medical staff of the prison administrations.

The General Population.

(For Statistical Tables, *see* pages 141 to 143.)

Registration of Vital Statistics.—Vital statistics have recently attracted a good deal of public attention on account of the discussion in the press of two topics of general interest. In England the decline of the birth-rate has been the subject of numerous articles, and in India attention was aroused by a statement that the progressive increase in the registered death-rates was a proof of the impoverishment of the mass of the Indian people.

It has become a proverb that anything may be proved by statistics, but this is really only another way of saying that they must be used with care. Vital statistics, unfortunately, present peculiar difficulties on account of the large number of special circumstances which must generally be taken into account before a conclusion can be drawn from them; for instance, one town may have a low birth-rate, and another a low death-rate; it is as wrong to condemn the former, before ascertaining that it contains the normal proportion of married couples at the reproductive ages, as it is to assume that the latter is healthy without finding out whether the low mortality is not due to the small numbers of young children and elderly persons in the population. Indian vital statistics present special difficulties. We have to depend upon the census population, because the registered returns are too inaccurate to allow of calculations of intercensal populations, with the result that as the decennium advances rates become unduly high; figures have been registered in certain areas for many years, but registration is even now not universal; the facts are nearly everywhere collected by an unpaid and generally illiterate agency; registration is compulsory only in the towns where the municipal authorities seldom enforce the bye-law; and the different social customs of the people often render the application of experience gained elsewhere misleading.

There is often greater difficulty, especially in towns, in obtaining information regarding births than deaths, and consequently infantile mortality which is calculated from the numbers of births and deaths of infants registered during the year, is excessive.

It is not possible here to detail the allowances which must be made in respect of the registration figures, but it seems necessary to explain, that however valuable they may be for the purpose of comparing the condition of the people in a province from year to year; and, due allowances being made, for comparing the condition of the populations in different provinces in any year, the figures registered are not yet generally accurate, and the degree of accuracy differs in the various provinces. This will be appreciated after reference to the following statement which gives the registered birth and death-rates per 1,000 of the population in three of the larger provinces in the years 1885, 1895, 1904, and 1905.

Year.	Madras.		Bengal.		United Provinces.	
	Birth-rate.	Death-rate.	Birth-rate.	Death-rate.	Birth-rate.	Death-rate.
	Per 1,000 of population.					
1885	29·3	21·8	24·71*	22·74	41·24	31·98
1895	29·1	19·6	34·59	31·39	34·90	29·13
1904	30·7	22·5	42·59	32·45	46·67	34·70
1905	32·0	21·4	39·55	38·63	41·24	44·00

(Figures for 1904 are given because the area of collection in Bengal in 1905 was not the same as in the earlier years, and because the death-rate in the United Provinces in 1905 is exceptionally high.)

It will be observed that in Bengal both birth and death-rates have risen greatly, while in Madras and the United Provinces the increase is comparatively small. In the United Provinces registration in 1885 was fairly good, and little improvement has taken place; in Bengal registration has improved from year to year, and

* For towns only.

in Madras the improvement has been inconsiderable. We may compare these rates with those calculated by Mr. Hardy and published in his actuarial reviews of the census figures of 1881, 1891, and 1901. As registration improves, the registered birth and death-rates will approximate the calculated rates.

Year.	Madras.		Bengal.		United Provinces.	
	Birth-rate.	Death-rate.	Birth-rate.	Death-rate.	Birth-rate.	Death-rate.
	Per 1,000 of population.					
1881	50·4	44·5	47·9	39·9	45·1	41·9
1891	50·3	36·0	51·8	44·8	44·2	37·7
1901	44·8	38·1	43·9	38·9	44·7	43·4

The statement of registration figures shows that in Bengal not only the registered death-rates, but the birth-rates also, increased, and it has been ingeniously argued that the increased birth-rate is only another proof of the impoverishment of the people. This argument is founded upon a proposition that the fecundity of the human animal and of all other living beings is in inverse proportion to the quantity of nutriment available, and that an underfed population multiplies rapidly. Even if this proposition was true the inference that the rising registered birth-rate in India is due to privation is easily demonstrated to be false, unless it is the case that the high Indian marriage-rate is the result, not of religious observance, but of recklessness induced by poverty.

A physiological stimulus must affect the individual, and to sustain the theory that privation causes the high birth-rate in India, Indian women should be exceptionally fertile. This they are not: the average Indian woman is apparently not much more fertile than the average woman in the England of vanishing birth-rates.

Fertility of Indian Women.—In England in 1851 the percentage of all women between the ages of 15 and 45 who were married was 47; this figure rose to 50 in 1871, but it fell again to 47 in 1891, and has not risen again. It is fair to reduce the reproductive period in India by five years, and take the proportion of all Indian women between the ages of 15 and 40, who are married. In India, excluding Burma, in 1891 this was 82·7 per cent. Of every thousand women at the reproductive age only 468 are married in England while 827 are married in India. In England in the sixties the number of legitimate births for every thousand married women at the reproductive age was about 305, in the nineties the figure had fallen to about 262, and in 1901 it had fallen to 235. In India, as the registered birth-rate is below the actual, we may accept the rate deduced by Mr. Hardy, which, including all live births, is 44·4 per thousand of the population. If this rate is correct, the number of children born for every thousand married women at the reproductive period is 273·6.

The high Indian birth-rate, then, is not due to exceptional fertility, but to the large proportion of married women. This has, of course, a bearing upon the high infantile death-rates, for a large proportion of all births must be the first children of youthful parents. The children of young parents are generally weak, and the first child of a marriage is especially exposed to the effects of ignorance and inexperience. The average birth and death-rates in India in Mr. Hardy's opinion do not give any indication of permanent change. A high birth-rate involves either a correspondingly high death-rate or an increase in the population so rapid as to encroach upon the limits of subsistence. The high birth-rate, as we have seen, is the result of the high marriage-rate, which may have been necessary if man was to contend successfully with the adverse physical conditions of his environment. When man in India has learned to protect himself against adverse physical conditions, marriage will be deferred, and the birth-rate, and with it the death-rate, will fall.

The existing system of registration.—The statement on the following page gives details regarding the agencies employed in the collection of vital statistics. It will be observed that, except in Madras and Coorg, the police are employed practically at all stages.

Province.	Collecting and Reporting agency.		Recording Agency.		Collating Agency.		Inspecting Agency.	
	Rural areas.	Town areas.	Rural areas.	Town areas.	Rural areas.	Town areas.	Rural areas.	Town areas.
Assam	Village officials ...	Head of households generally.	The Police station	The Police station, the Magistrate or Municipal office.	The Deputy Commissioner or Sub-divisional officer.		Deputy Commissioner, Sub-divisional officers and the ordinary revenue and police agency. Inspectors of Vaccination are required to test entries in registers.	
Bengal	Village Chaukidars ...	Town Police	Police Station ...	Police Station ...	Civil Surgeon ...	Civil Surgeon ...	The Police and other local officers and the vaccinating staff.	
United Provinces ...	Village Police. In hill tracts village headmen.	Town Police, heads of households and sweepers.	Reporting officers maintain permanent registers.		Civil Surgeons who are generally the health officers.		Revenue and Police officers, officers of the Sanitary and Medical Departments, the vaccinating staff and members of municipal and district boards.	Civil Surgeons generally, and also members of district and municipal boards.
Punjab	Village Chaukidar ...	Municipal Committees responsible. In Municipalities where no byelaws are in force, the beat constable assisted by the mohalla sweepers.	The Police Station	Municipal office ...	Civil Surgeons		Officers of the Sanitary Department, Civil Surgeons, superior police officers, revenue officers and the members of the Vaccination Department.	
North-West Frontier Province.	Village Chaukidar ...	Heads of households	Police Station ...	Municipal office ...	Civil Surgeons		The Revenue Staff under the control of the Deputy Commissioner, the Civil Surgeon and his subordinates including the vaccinating staff, members of municipal and district boards, and local men of position.	
Central Provinces ...	Village watchman (Kotwar).	Heads of households	The Police Stations		Civil Surgeons ...		Revenue and police officers, Civil Surgeons and Superintendents of Vaccination.	
Berar	Headman of village (patel).	Headman of town (patel).						
Madras	Headmen of villages (Kamans).	Heads of households	Headmen (Kamans) who report to the Collectors.	The Municipality...	Collectors and Municipalities who transmit returns to the Sanitary Commissioner.		Collectors and divisional officers, Tehsildars and Deputy Tehsildars, Revenue Inspectors and Deputy Inspectors of Vaccination.	
Coorg	Village headman (patel) managers etc., on coffee estates.	Municipal and Medical authorities.	Officer in revenue charge of a collection of villages.	Municipality ...	The Civil Surgeon		The Commissioner and other superior revenue officers. The Civil Surgeon and the vaccinating staff.	
Bombay	The Police Patel (headman) and the Kulkarni (Acct). Pound Munsiffs and village School Masters are also employed in Sind.	Municipalities ...	The Police Patel or Kulkarni (the Accountant).	Municipalities ...	Deputy Sanitary Commissioner ...		Officers of the Revenue and Sanitary Departments, the latter including the Vaccination Department.	
Burma	Village headman ...	Headmen of wards ...	Village and ward headmen record entries, copies of which are made over to the beat patrol for submission to the police stations		Township officer for submission to the Civil Surgeons.		Township and Sub-divisional officers under control of the Deputy Commissioners.	

If the existing system worked perfectly we should obtain complete information regarding the number and sex of infants born, and the number and sex of the persons that die, and we should have a general idea of the causes of death, but the existing system does not yet work perfectly, and very often the results obtained are misleading. It is evident, moreover, that there is a point beyond which the present system of registration of vital statistics cannot go; however perfectly it may work, it cannot give us accurate details of the causes of death; to obtain this information a professional agency is necessary. It is impossible at present to employ a professional agency, except in the larger towns, and the best way to render the statistics, as at present collected, intelligible seems to be to employ a professional agency in selected areas. The collection of facts in these areas by the existing agency would continue, and the comparison of the statistics collated by the two agencies would give a key to the interpretation of the general statistical returns.

Registration by a Professional Agency.—An experiment on these lines is being carried out in Bengal, in the Galsi *thana* in Burdwan. The following analysis of the registration results collected in August is interesting. There were in all 72 deaths, all of which, except one from malarial fever, had been duly registered in the *thana*. The diseases shown in the *thana* register were fever 52, "other causes" 9, cholera 3, diarrhœa 3, dysentery 2, respiratory disease 1, and measles 1. Enquiry into the real causes of death showed that the entries regarding cholera, diarrhœa, dysentery, and measles were correct, the nine deaths from "other causes" were due to infantile diarrhœa and diseases of newly-born children. The 52 deaths from fever included malarial fever 12, pneumonia 8, diarrhœa 6, tubercle of lungs 5, "senile decay" 4, and single cases of cholera, Brights disease, heart disease, &c.

A similar enquiry is being carried on in one of the Bengal towns.

Revision of forms in use in the great towns.—A Conference, attended by the Medical Officers of Health of Calcutta, Madras, Bombay, and Rangoon, was held at Calcutta in November, 1904, for the purpose of preparing standard forms for the exhibition of vital statistics, &c., in municipal reports. A series of forms drawn up on the lines of the standard forms in use in the provincial sanitary reports was adopted, and the forms have been taken into use.

Births in India in 1905.—The total population of the areas under registration in the Indian Empire in 1905 numbered 223,124,252, but this figure makes no allowance for the natural increase which has occurred since the census was taken in the beginning of 1901. The number of births registered during the year aggregated 8,731,497, as compared with 9,136,536 in 1904, and the general birth-rate in 1905 was 39·13 per thousand or 1·73 per thousand lower than the birth-rate in the previous year. The decrease in the total number of births was due to a decline in the birth-rate in Bengal, Eastern Bengal and Assam, the United Provinces, and Bombay; in all other parts of the Empire, except the Upper Burma towns, where registration is defective, the numbers of births registered were greater in 1905 than in the previous year. The extreme birth-rates were 54·02 per thousand recorded in the Central Provinces and Berar, where the birth-rates of recent years have been extraordinarily high, and 25·31 in the small province of Coorg, where the sex distribution of the population is peculiar and registration is defective. In most of the other provinces, the rates were not far from the mean, those furthest from it being the Punjab and Madras with birth-rates of 44·4 and 32·0 per thousand, respectively. In three provinces the birth-rates were lower than the death-rates, namely, the Punjab where the birth-rate fell short of the death-rate by 3·2 per thousand, and the United Provinces and Coorg where the deficiencies were 2·76 and ·92, respectively. In the 12 towns in Upper Burma the registered death-rate was 2·0 per thousand higher than the registered birth-rate. In the remaining eight provinces the excess of the birth over the death-rates ranged from 16·81 per thousand in the Central Provinces and Berar to 1·02 per thousand in Bengal. The mean number of male births recorded in India generally for every 100 births of females was 106·61. The highest percentages were 122·6 in the North-West Frontier Province, and 116·10 in Ajmer-Merwara and the lowest 95·22 in Coorg; in the other provinces the percentages varied between 109·8 in the Punjab and 103·9 in the Madras Presidency.

Deaths in India in 1905.—The total number of deaths registered was 8,117,771, and the mean death-rate was 35·96 per thousand as compared with 7,436,472 deaths, and a mean death-rate of 32·86 in 1904. In all provinces except Bombay, Madras,

Coorg, the Punjab, and the North-West Frontier Province, the death-rates of 1905 were higher than those of the previous year, the decline in Bombay and the Punjab being due to the abatement of plague, and in Madras, the North-West Frontier Province and Coorg to a decrease under the heading fevers. The highest death-rates were 47·55 per thousand in the Punjab, 44·0 in the United Provinces, and 38·53 in Bengal; and the lowest were 24·93 in Lower Burma, 22·46 in Upper Burma, and 21·4 in Madras. In every province, except Eastern Bengal and Assam, the urban were higher than the rural death-rates.

The highest mortality in India generally occurred in April, and the lowest in July. In most provinces the death-rates of males were higher than the death-rates of females, but in the United Provinces, the Punjab, the North-West Frontier Province, Coorg, and Ajmer-Merwara the female rates were the higher, the excess being most remarkable in the Punjab where plague was most severe.

The death-rates of infants calculated upon the numbers of births and of deaths of infants registered during the year ranged among males and females, respectively, from 301·29 and 270·94 per thousand in the Central Provinces and Berar to 182·43 and 162·99 in Madras. It may be noted that the registered birth-rate was highest in the Central Provinces and Berar, and excepting Coorg, lowest in Madras; and that in the other provinces there is a relation between high birth-rates and high infantile death-rates. In all provinces, with the exception of Coorg, the birth-rates of males were higher than the birth-rates of females, and in all, except the Punjab, the male infantile death-rate was the higher, although in the United Provinces and Ajmer-Merwara the difference between the death-rates of male and female infants was small, and only in the Central Provinces and Berar and Lower Burma was the difference great. Cholera was most severe in Eastern Bengal and Assam (death-rate 4·77 per thousand), Bengal (2·93), and the United Provinces (2·55). Small-pox was present in every province and in five, Lower Burma (1·01), Bombay (·92), Coorg (·73), Central Provinces and Berar (·70), and Ajmer-Merwara (·58), the death-rates were over ·5 per thousand. Plague was absent, or practically absent, from Coorg, Eastern Bengal and Assam, and the North-West Frontier Province, and the plague death-rates were comparatively low in Madras (·2), Upper Burma (·22), and Lower Burma (·55). The mortality in the Punjab (16·65) was more than twice as high as in the United Provinces (8·05) where the next highest death-rate from plague was recorded; in the remaining provinces the plague death-rates ranged from 5·20 in Ajmer-Merwara to 1·07 in the Central Provinces and Berar. The fever death-rates were very low in Madras and Burma, and they were highest in the United Provinces and Bengal. A comparison of the rates registered under fever and "all other causes" in the different provinces shows that they vary inversely, but in most provinces "fever" is credited with the vast majority of all the deaths; in a few the registering agency is more discriminating—or discriminates in a different way. By far the highest death-rates from dysentery and diarrhœa were registered in the Central Provinces (3·02) and Bombay (3·0); in only two other provinces, Lower Burma (1·43), and Madras (1·4) was the ratio more than 1 per thousand, the rates in the other provinces ranging from ·90 in Bengal to ·28 in the North-West Frontier Province.

The death-rates registered as due to respiratory diseases were, in most cases, low, the highest being 3·05 per thousand in the Punjab and 2·95 in Bombay, both provinces where plague was severe.

Bengal.—The weather of 1905 was abnormal, and the climatic conditions were unfavourable to the public health. The early part of the year was exceptionally cold, and the rainfall was excessive; the south-west monsoon rains were not established until the end of June, which was extraordinarily hot, and although the well distributed copious rains of July and August and the very heavy fall in September gave a normal supply to the whole province except Orissa, where the defect was about 20 per cent., the monsoon rains ceased early, October being almost rainless. The late commencement and early cessation of the monsoon rains was unfavourable to many of the crops, and in Bihar the standing crops were damaged or destroyed by floods, the result being that the agricultural outturn was below the average in 23 districts, average in five, and above the average in only three. Owing to the absence of export, however, prices were only slightly raised in Bihar, Chota Nagpur, and Orissa, while they were easier in Lower Bengal.

The total population under registration in the remodelled province is 49,891,164. The number of births registered in 1905 among this population was 1,973,301, or 141,925 fewer than in the previous year, and the birth-rate was 39·55 per thousand against 42·39 in 1904 and a quinquennial mean of 38·91. The highest district death-rates were 51·33, 47·46, and 45·78 registered, respectively, in Palamau, Cuttack and Muzaffarpur, and the lowest, excluding the urban district of Calcutta, where the birth-rate was only 18·44, were 32·84, 32·20, and 30·49, registered in Burdwan, Hooghly and Jessore, respectively. The average recorded birth-rate in rural areas was 40·58 per thousand compared with a mean of 24·53 in the towns in which rates ranged from 65·17 in Jamalpur, 49·48 in Sahibganj, and 47·52 in Lohardaga to 5·28 in South Barrackpore. The explanation of the low rates in towns is the disproportionate male population, the practice of women leaving the towns to be confined at their homes in the districts, and inferior registration. The percentage of males to females was 105, ranging in the districts from 115 in Calcutta and 110 in Howrah to 101 in Gaya, Hazaribagh and Ranchi.

The number of deaths registered was 1,922,369, or 327,849 more than in 1904, and the death-rate was 38·53 per thousand, or 6·58 per thousand higher than in 1904, and 5·11 higher than the mean of the quinquennium. The highest district rates were registered in Gaya, 59·86 per thousand, Patna 58·74, and Shahabad 58·65, all districts in the west of the province where plague was severe, and the lowest in Manbhum 26·23, Ranchi 25·50, and Singbhum 22·05. In rural areas the mean death-rate was 38·42, compared with 40·01 per thousand in the towns, among which enormous rates, such as 92·26 in Daudnagar, in the Gaya District, 87·91 in Gaya town, and 83·46 in Revelganj in Saran, where plague or cholera, or both, were epidemic, are contrasted with rates such as 10·77 in Cossipore-Chitpur, 10·52 in Maniktola, and 7·41 in Ulubaria, where the low rates are evidence rather of defective registration than exceptional salubrity.

The highest mortality in the province as a whole occurred in October, November, and December, and the lowest in June, July, and August.

Among the sects Hindus (39·22 per thousand) and Muhammadans (38·58) had the highest death-rates; the rates among "Other Classes" (27·80), Buddhists (24·66), and Christians (21·66) being much lower.

Infants under one year of age died at the rates of 216·56 and 200·42 per thousand of males and females born, respectively; as usual in Bengal the recorded male rates were the higher at all age periods, the mean death-rate among males being 40·07 per thousand compared with 37·00 among females.

Eastern Bengal and Assam.—The number of the population among whom vital statistics are registered in Eastern Bengal and Assam is, excluding 89,012 in certain hill tracts, 29,812,735. In 1905 there were registered 1,173,879 births, equal to a birth-rate of 39·37 per thousand as compared with 41·68 in the previous year, and 39·53, the mean of the previous five years. As in Bengal, the climatic conditions of the year were unfavourable, and heavy floods in the districts bordering the Brahmaputra and Meghna not only damaged the crops, but apparently led to a severe epidemic of cholera in the last quarter of the year.

The highest district birth-rates were 50·70 per thousand in Goalpara, 48·29 in Malda, and 45·25 in Noakhali; and the lowest were 30·46 in Pabna, 30·06 in Sibsagar, and 28·96 in Kamrup. In rural areas the mean death-rate was 39·72 per thousand, whereas in the towns, in which rates ranged from 69·16 in Barpeta to 1·71 in Jhalakati, the mean was only 23·40. The percentage of male to female births was 106.

The registered deaths numbered 1,045,305, the death-rate being 35·06 per thousand compared with 32·11 among the same population in 1904, and 31·52, the mean of the quinquennium. Among the districts the highest rates were 45·59, 44·45, and 43·88, registered in Pabna, Goalpara, and Malda, respectively, and the lowest were 25·05, 24·77, and 19·99 in Cachar, Sibsagar, and Nowgong. The mean death-rate in rural areas was 35·25, in remarkable contrast to the mean in the towns, where it was only 26·42. The highest urban rates were 55·21 in Barpeta, and 53·44 in Mangaldai, and the lowest 7·27 in Pabna, and 4·77 in Jhalakati. The lowest monthly death-rate was registered in March, 1·97, and the highest rates were registered in November, 4·29, and December, 4·78. Muhammadans died at the rate of 36·38 per thousand, "Other Classes" at the rate of 36·76, while the registered rates among Christians and Buddhists were 25·69 and 18·75 respectively.

Male infants died at the rate of 211·81, and female infants at the rate of 194·59 per thousand born, respectively; at all age periods, except the three between 15 and 40, the male death-rates were the higher—males dying at the rate of 35·86 and females at the rate of 34·22 per thousand.

Tea gardens.—The mean annual strength of the coolies employed on tea gardens in Assam, during the twelve months ending the 30th June, 1906, rose from 660,700 to 670,963. Of the total labour force 38·85 per cent. was employed in the Surma Valley, and 61·15 per cent. in the Assam Valley, the distribution approximating closely to that of the preceding year. The birth-rate showed an increase, being 29·2 per thousand of the total population, and 94·7 per thousand of the female adult population, against 28·4 and 92·1 per thousand respectively in 1904-05. These rates compare unfavourably with the corresponding provincial ratios of 39·37 and 128·4.

The registered death-rate 24·0 per mille was the same as in the previous year, the total number of deaths being 16,103. The principal causes of death were dysentery (2,843), malarial fever (2,429), cholera (2,057), diseases of the respiratory organs (1,933)), diarrhœa (1,607), and anchylostomiasis (1,499). The death-rate among coolies from all recruiting areas, except the Central Provinces, showed a slight increase. The mortality among coolies from those provinces fell from 35·69 per mille to 31·18.

The number of unhealthy gardens, *i.e.*, those with a death-rate of over 70 per mille, was 10 of a total of 757, against 6 of a total of 776 in the year preceding. There were 58 deaths among coolies journeying to the Assam Valley, against 16 in the previous year; 45 of these deaths were due to cholera. Four coolies died of cholera at the Sylhet depôts.

United Provinces.—The climatic conditions of the year were unfavourable; an exceptionally cold and wet spring was followed by very hot weather in May and June; the monsoon rains began late, were in defect in many districts, and ceased to fall before the usual time, except in the Benares division, where the September rainfall was 70 per cent. in excess of the normal. Harvests generally were bad, and prices were high. The number of births registered was 1,967,009, and the birth-rate which had risen to 46·67 per thousand in 1904 as compared with a quinquennial mean of 44·07 fell to 41·24. The highest district rates were 52·59 in Jhansi, 51·44 in Bijnor and 51·32 in Shahjehanpur, and the lowest 32·15 in Ballia, and 31·96 and 27·86 in Naini Tal and Dehra Dun, respectively.

In towns the mean birth-rate was 38·82. Among the towns there were nine, including Kairana (56·26), Chandpur (55·78) and Konch (54·25), in which the birth-rates were over 50 per thousand; in Brindaban (19·81), Naini Tal (15·24) and Mussoorie (9·16) the rates were exceptionally low. The mean percentage of male to female births registered was 108·39.

The registered deaths numbered 2,098,300, or 443,351 more than in 1904, and the death-rate was 44·0 per thousand, nearly 9 per mille higher than the rate of the previous year, 34·70, which was slightly higher than the quinquennial mean, 33·80. By far the highest district death-rate was 91·01, recorded in Muttra where the plague death-rate was 62·64; in the other districts death-rates ranged from 66·58 in Sultanpur, where there was a death-rate from cholera of 25·30 per thousand, and 65·38 in the Ghazipur district of the Benares division, where plague and cholera were severe and fevers exceptionally prevalent, to 26·12 in Almora, the only district in the province in which no death from either plague or cholera was reported. The rural mean death-rate was 43·26 compared with 53·64 in the towns in which, excepting Kiratpur (105·71), where the plague death-rate was 71·82 per thousand, and Brindaban (95·61), where the plague death-rate was 41·51, the death-rate ranged from 86·35 in Muttra to 23·64 in Laharpur.

The highest mortality was recorded in March, 5·07 per thousand, and the lowest, 2·39, in August.

Hindus died at the rate of 44·21 and Muhammadans at the rate of 43·66, "Other Classes" and Christians at the rates of 27·13 and 9·67, respectively.

Infants died at the rates of 264·21 and 261·48 per thousand boys and girls born, respectively. At all age periods except in infancy and after 50 the female death-rates were the higher; females dying at the rate of 45·44 per thousand, compared with a rate of 42·64 among males.

Punjab.—The first three months of 1905 were stormy and exceptionally cold; in April the temperature was comparatively low, but May and June were unusually hot. The rains failed in July and August, but in September a storm gave a very

heavy fall. The temperature of October and November was much higher than usual. The heat and dryness of the summer and autumn were attended by a remarkable reduction in the prevalence of plague.

The number of births recorded was 893,360, and the birth-rate was 44·4 per thousand compared with 41·5 in the previous year and 40·5, the mean of the previous five years. In the districts the highest birth-rates were 67·2 in Lyallpur, 51·2 in Sialkot and 48·5 in Multan; the lowest being 36·2, 35·2 and 21·4 in Ambala, Dera Ghazi Khan and Simla, respectively. The mean rural birth-rate was 44·7 compared with 41·3 in the towns. The percentage of male to female births was 109·8, the district percentages ranging from 118 in Dera Ghazi Khan to 105 in Ludhiana and 104 in Simla.

The number of deaths recorded was 956,108, more than 30,000 less than in 1904, and the death-rate fell from 49·1 per thousand in that year to 47·6, against a quinquennial mean of 44·9. The plague death-rate was 16·7 per thousand, so that, so far as the mortality figures go, the year, but for the presence of plague, would have been an exceptionally healthy one. The highest district death-rates were 78·5 registered in Rohtak, 71·3 in Gurgaon and 66·1 in Amritsar; and the lowest were 25·4 in Dera Ghazi Khan, 25·0 in Simla and 24·5 in Jhang. The mean death-rate in rural areas was 47·37, and the urban rate was 49·13. The enormous death rate of 306·6 was registered in Kangra where 1,374 persons lost their lives as the result of the great earthquake of April, 1905; and in Dharmsala where many people were killed, the death-rate was 90·02. In Sangla, a very small town in Gujranwala, high mortality from plague, cholera, small-pox and fevers gave a death-rate of 129·33 per thousand, and in Hansi, where the plague death-rate was 78·86 per thousand, the total death-rate was 120·86. Death-rates of 104 were registered in Sharakpur and Khudian in the Lahore district; in other towns the death-rates ranged from 81·85 in Bahadurgarh to 7·10 in Khangah Dogran in Gujranwala.

Hindus died at the rate of 51·48 per thousand and Muhammadans at the rate of 44·21; Christians and "Other Classes" (in whose case there are errors in classification) dying at the rates of 24·30 and 54·74, respectively. The highest monthly death-rates were recorded in April, 8·67, and May, 7·35, and the lowest in September, 2·20 and October, 2·37.

Male and female infants died at the rates of 233·90 and 236·31 per thousand born, respectively; and boys and girls over one year and under five years of age died at the rates of 57·39 and 61·42. At all age periods the death-rates of females were the higher, the general death-rate among males being 44·1 and among females 51·6 per thousand.

North-West Frontier Province.—The number of births registered was 70,369 and the birth-rate was 35·4 per thousand, compared with 34·9 in 1904, and the quinquennial mean of 32·3, the general increase in the figures being due to the efforts made to improve registration. The highest district birth-rate was 43·3 recorded in Kohat and the lowest 31·7 in Hazara. The percentage of male to female births was 122·6, the percentages varying in the districts from 134·0 in Peshawar to 114·0 in Dera Ismail Khan. Special enquiries have been carried out during the past few years with the object of ascertaining how far the high recorded proportion of male to female births represented the facts. In 1905 these special enquiries were continued, and two areas were selected, one in the Kohat district containing 30 villages and another in Peshawar containing 159 villages, most of the villagers in both areas being Pathans. The population of the selected area in Kohat was 25,070 (13,514 males and 11,556 females) and during the time of the enquiry the births of 472 males and 428 females were registered by the *chowkidars;* it was found that the births of 43 males and of 40 females had not been registered. The percentage of male to female births according to the *chowkidars'* returns was 110·3, according to the corrected figures it was 110, the mean rate for the whole district being 124·3. The population of the selected area in Peshawar was 79,001 (41,946 males and 37,055 females). The *chowkidars* registered the births of 1,499 males and 1,167 females, a percentage of males to females of 128·4; it was found that the births of 116 males and 101 females had not been registered and when these are included the percentage falls to 127·4, the mean rate for the whole district being 134·0. The results in both areas appear to show that the percentage of male to female births in the frontier districts is really very high, but that registration

is carelessly performed, the fact that lower proportions of male births occurred in the selected areas than in the surrounding districts suggests the possibility of exceptional diligence on the part of the *chowkidars*.

The number of deaths registered was 53,327, and the death-rate was 26·8 per thousand, compared with 28·6 in the previous year and 25·5, the mean of the previous five years. The rates varied in the districts between 27·6 in Peshawar and 24·5 in Bannu, and in the towns between 44·25 in Buffa in Hazara, and 16·77 in Kulachi in Dera Ismail Khan. The death-rate among Muhammadans was 27·23, but they are perhaps less careless regarding registration than the comparatively small number of Hindus, among whom the death-rate was 23·12. Male infants died at the rate of 203·25 and females at the rate of 192·89 per thousand born. In all age periods except under one year, 1—5 and 50—60, the female death-rates were the higher, the general death-rates being 26·2 per thousand among males and 27·5 among females.

Central Provinces and Berar.—The cold weather rains were favourable and but for the extreme cold in February the wheat crop would have been exceptionally good. The monsoon rains were late and the fall was defective until the heavy rain of September to which the prevalence of malarial fevers is attributed. The autumn crops were abundant. The year was unhealthy, and influenza, malarial fevers and bowel complaints were rife.

The number of births recorded was 642,199 and the birth-rate was 54·02 per thousand against 53·19 in 1904. In the districts of Yeotmal, Damoh and Murwara, the high birth-rates of 61·24, 60·00 and 59·86 were recorded, while the lowest rates in the province were comparatively high—48·69 in Hoshangabad, 48·57 in Amraoti and 46·30 in Burhanpur, the only district in which the births were fewer than the deaths. In rural areas the mean birth-rate was 55·34 compared with 42·37 the urban mean. The provincial percentage of male to female births was 104·38, varying in the districts between 108·91 in Nagpur and 102·14 in Raipur.

The registered deaths numbered 442,383, and the death-rate was 37·21 per thousand, compared with 32·06 in the previous year. The highest district death-rates were 54·80 recorded in Burhanpur and 50·08 in Buldana; in the other districts the rates ranged from 47·19 in Nimar to 28·44 in Mandla. In rural areas the mean death-rate was 36·69 as compared with 41·87, the mean in the towns, among which very high rates were registered in Mohgaon (127·05), a small town which suffered severely from plague, in the Chhindwara district, in Nandura (93·12) and Deulgaon Raja (89·15), small towns in the Buldana district, where plague was very severe in both town and country. In the remaining towns the death-rates ranged from 82·68 in Akote to 17·07 in Rajim.

The infantile death-rate was 301·29 among males and 270·94 among females per thousand born, respectively. Males of all ages died at the rate of 39·35 and females at the rate of 35·12 per thousand of the census population.

Madras.—The rainfall in the presidency in 1905 was about three and a half inches below the normal, but the rainfall of both monsoons was irregularly distributed and the prices of food grains, which had risen on account of the failure of both the south-west and north-east monsoons in 1904, rose still further.

The total number of births recorded was 1,176,256, equal to a birth-rate among the population of 36,737,533 under registration of 32·0 per thousand—the highest rate yet reached excepting the year 1891 when it was 32·4—as compared with 30·7 in 1904 and 29·4, the quinquennial mean. Excluding the urban district of Madras, where the birth-rate was 46·0 per thousand, the district rates ranged from 38·7 in Guntur to 24·4 in Nellore. The mean rural birth-rate was 31·6 against 35·1 in the towns in which rates varied between 61·2 in Vaniyambadi and 6·5 in Madanapalli in Cuddapah.

The percentage of male to female births was 103·9, the district percentages ranging from 107·7 in the Nilgiris to 101·5 in Anantapur.

The deaths registered numbered 786,123 and the death-rate was 21·4 per thousand against 22·5 in the previous year, and 21·9 the average of the previous five years. Again excluding Madras, where the death-rate was 59·5 per thousand, the district rates ranged from 31·4 in Bellary to 16·0 in North Arcot. In rural areas the mean death-rate was 20·3, while in the towns the mean was 29·6, the extreme rates being 92·2 in Kampli in Bellary and 5·6 in Rajampet in Cuddapah.

Muhammadans and Hindus died at the rates of 23·3 and 21·4, respectively; Christians and "Other Classes" at the rates of 17·2 and 9·2.

Male infants died at the rate of 182·43 per thousand born, female infants at the rate of 162·99. In the three age periods between 10 and 30 the female death-rates were the higher, in all other age periods males died at the higher rates, the general death-rates being 22·2 and 20·6 per thousand among males and females, respectively.

Coorg.—There were 4,572 births registered in Coorg in 1905 equal to a birth-rate of 25·31, as compared with 21·97 in the previous year and 23·28 the mean of the previous five years. The district rates varied between 38·15 in Padinalknad and 19·90 in Yedenalknad, the mean percentage of male to female births being 95·22.

The number of deaths registered was 4,739 and the death-rate was 26·24, against 26·62 in 1904 and a quinquennial mean of 31·30. The highest district death-rate was 30·74 in Nanjarajpatna, the lowest 23·66 in Kiggatknad; the mean urban death-rate was 32·13, the mean rural rate, 25·70. Male and female infants died at the rates of 222·42 and 209·22 per thousand born, respectively. In all age periods, except the four from 10 to 40, the male death-rates were the higher, but the general death-rate of males was 25·70 as compared with 26·91 among females.

Bombay.—The number of births recorded in the Bombay Presidency fell from 648,594 in 1904 to 611,173 in 1905, and the birth-rate from 35·09 to 33·07 per thousand, which, however, is considerably higher than the quinquennial mean, 30·51. The highest district birth-rates were 46·63, 45·09 and 43·12 registered in Khandesh, Broach and Panch Mahals, respectively, and the lowest were 19·67, 19·04 and 17·88 in the Sind districts of Upper Sind Frontier, Hyderabad and Thar and Parkar. The mean birth-rate in rural areas was 34·07; the mean of the urban rates was much lower, 26·42 per thousand, the highest rates being 51·60 in Karachi, 51·43 in Dholka in Ahmedabad and 44·29 in Athni in Belgaum. The percentage of male to female births in the presidency generally was 108·44, but in the districts of Bombay proper the percentages varied between 111·72 in Kaira and 102·43 in Panch Mahals, while in the Sind districts, excluding Karachi where the percentage was 114·5, the percentages ranged from 135·81 in Hyderabad to 121·13 in Sukkur.

There was a most gratifying decline in the mortality, the number of deaths falling from 764,914 in 1904 to 588,394 in 1905, and the death-rate from a mean of 46·31 in the previous five years and 41·39 in 1904 to 31·84. The fall in the mortality was due to the abatement of the plague, the recorded deaths falling by 152,594 from 223,957 in 1904 to 71,363. The highest district death-rate was, excluding 62·33 in Bombay City, 41·13 in Ahmedabad; in the remaining districts the rates ranged from 40·10 in Khandesh to 15·88 in Hyderabad. In rural areas the mean death-rate was 29·47 compared with 47·59 in the towns, among which the highest rates were 65·24 in Shikarpur, 63·43 in Ahmedabad, towns in which small-pox and diseases recorded under the heading "fevers" were exceptionally severe, and 63·05 in Yeola, a small town in Nasik, where the plague mortality was 38·41 per thousand.

Hindus died at the rate of 34·0 per thousand, followed by Jains, 28·80, Parsis 24·26, Muhammadans 23·98, and Christians 22·76. The high rate recorded for "Other Classes," 48·18, is dependent upon errors in classification.

The death-rate of male infants was 229·52 and of female infants 219·07 per thousand born, respectively. In all age periods except 5—10, 10—15, 15—20 and 20—30 the male death-rates were the higher, the means being 32·11 among males and 31·54 among females.

Lower Burma.—The number of births registered in Lower Burma in 1905 was 191,226, about 11,200 more than in the previous year, and the birth-rate rose from 32·71 per thousand to 34·34 as compared with the quinquennial mean of 33·46. In the districts, excluding Rangoon, the rates ranged from 42·73 in Thayetmyo to 27·72 in Toungoo, the mean percentage of male to female births being 106.

The registered deaths numbered 138,850 and the death-rate which was 22·36 per thousand in 1904, as compared with a mean of 23·17 in the five years ending with 1904 rose to 24·93. Excluding the urban district of Rangoon, where the death-rate was 45·90, the district rates varied between 28·99 in Henzada and 15·59

in Thaton. In rural areas the mean death-rate was only 23·0 as compared with 38·21 in the towns, among which Wakema (54·53), Kyaiklat (53·05) and Henzada (49·32), in the Irrawaddy division, where cholera and small-pox were severe, suffered the heaviest mortality.

The death-rate among Hindus was 32·03, among Burmese 24·87, among Muhammadans 22·99, among Christians 15·36, and among "Other Classes" 26·90.

The infantile death-rate was 220·17 for males and 171·64 for females per thousand born, respectively. In all age periods the male death-rates were the higher, the general death-rate for males being 26·43 and for females 23·24.

Upper Burma.—The registration of births in Upper Burma is limited to twelve towns, but will become general from 1st January, 1907. The mean birth-rate in the twelve towns fell from a quinquennial mean of 37·03 per thousand and 35·05 in 1904 to 34·91 in 1905 the rates ranging in the individual towns from 50·33 in Taungdwingyi to 29·09 in Shwebo; and the percentage of male to female births ranged from 112 in Pakokku to 79 in Salin.

The total number of deaths recorded was 65,541, and the death-rate rose from 18·69 to 22·46 as compared with a quinquennial mean of 19·63. The district death-rates varied greatly from 30·49 in Kyaukse to 15·41 in Meiktila. The rural death-rate was 20·87, while the mean rate in the towns was 36·56, the rates ranging in individual towns from 62·55 in Pakokku, where cholera was severe, 50·53 in Pyinmana, where plague was epidemic, and 49·07 in Myingyan, which suffered from cholera, to 24·08 in Yamethin.

The Burmese death-rate was 22·46, as compared with 22·12 among Hindus, 23·25 among Muhammadans and 13·36 among Christians.

The defective registration of births renders an estimate of the infantile death-rate impossible. At all age periods, except 30—40, the male death-rates were the higher, the general death-rate being among males 23·64 and among females 21·40 per thousand.

Ajmer-Merwara.—The number of births recorded rose from 15,997 in 1904 to 17,802, and the birth-rates from a quinquennial mean of 26·38 and 33·54 in 1904 to 37·32 per thousand in 1905, the rate being 45·70 in Merwara and 34·84 in Ajmer. The percentage of male to female births was 112·16 in Merwara and 117·66 in Ajmer.

The number of deaths registered was 16,332, or 3,183 more than in the previous year, and the death-rate was 34·25 compared with 27·57 in 1904 and a quinquennial mean of 51·75. The death-rate in Ajmer, where plague was widespread and gave rise to a death-rate of 6·51, was 36·32 per thousand, against 27·25 in Merwara. Plague was very severe in the small town of Kekri where the death-rate from all causes was 105·20. In Ajmer suburb the total death-rate was 67·72, including 7·12 from plague and 2·99 from small-pox. The Hindu and Muhammadan death-rates were, respectively, 35·98 and 35·53 per thousand.

The death-rates of infants were 234·32 among males and 232·94 among females per thousand born, respectively. In the five age periods between 1 and 30 the female death-rates were the higher, the general rates being among males 33·66 and among females 34·90 per thousand.

LIBRARY OF THE BOMBAY BRANCH OF THE ROYAL ASIATIC SOCIETY

History of the Chief Diseases.

(For Statistical Tables, *see* pages 144 to 148.)

Mortality from Chief Diseases.—The following statement gives a tabular view of the number of deaths from, and the death-rates per 1,000 of population for each of the chief diseases and all causes recorded in British territory in India during each of the five years, 1901-5. It will be seen that the year under review was

Years.	Cholera.	Small-pox.	Fevers.	Dysentery and Diarrhœa.	Plague.	All Causes.
1901	271,210	89,385	4,174,919	247,190	237,688	6,606,387
	1·21	·40	18·62	1·10	1·06	29·46
1902	224,136	115,443	4,279,351	235,750	456,975	7,112,336
	·99	·51	18·95	1·04	2·02	31·49
1903	312,854	93,693	4,459,237	273,459	686,485	7,881,125
	1·38	·41	19·66	1·21	3·03	34·7
1904	192,835	55,232	4,093,981	240,655	940,609	7,436,472
	·85	·24	18·09	1·06	4·16	32·86
1905	441,786	70,962	4,417,655	264,124	940,821	8,117,771
	1·96	·31	19·57	8·17	4·17	35·96

exceptionally unhealthy; the death-rate (35·96) is the highest in the quinquennial period. Compared with the previous year, 681,299 more deaths were recorded, and there was an increase in the mortality under each heading, this increase being least significant (·01 per mille) in the case of plague: compared with the preceding years of the quinquennium, the mortality from cholera, from plague, from fevers and from dysentery and diarrhœa has been excessive; the death-rates from cholera and plague are the highest in the quinquennium, and the death-rates for fevers and dysentery and diarrhœa are second only to the death-rates from these causes in 1903. Fevers accounted nominally for more than 54 per cent. of the deaths from all causes.

Cholera in India in 1905.—The number of deaths from cholera recorded in British territory during 1905 was 441,786, equal to a death-rate of 1·96 per 1,000 of the total population under registration. If the deaths recorded in the native States from which returns were received are added, the total amounts to 442,506. In the previous year 192,835 deaths from cholera were recorded in British territory, giving a ratio of ·85 per 1,000 of population, so that during the year under review cholera was considerably more than twice as prevalent as in the previous year. This increase in mortality during 1905 was shared by all the British provinces except Ajmer-Merwara and Coorg, both of which have now remained free from the disease for three year in succession. The greatest numbers of deaths from the disease during the year were recorded in Bengal, Eastern Bengal, and Assam, the United Provinces and Madras, the figures requiring special notice being 142,312 deaths reported from the new province of Eastern Bengal and Assam and 121,790 deaths reported from the United Provinces as compared with 6,617 from the same province in 1904. The highest death-rates were recorded in Bengal, Eastern Bengal and Assam, the United Provinces and Lower Burma, and in all these provinces cholera was present throughout the year. The seasonal prevalence varies widely—not only in the different provinces in the same year, but also in the same province from year to year. In Bombay the greatest number of deaths occurred in June as compared with August in 1904; in Madras in August as compared with January in 1904; in the Punjab, the North-West Frontier Province and the Central Provinces in September as compared with June, July, and August, respectively, in 1904; in Lower Burma in October as compared with April in 1904, in Bengal and the United Provinces in November as compared with December and June, respectively, in 1904; in Eastern Bengal and Assam in December, the same month as in 1904. In Bengal during 1905, fewest deaths occurred in the month of June, while in September and October, the two months during which the disease is usually least prevalent, a heavy incidence was recorded.

Cholera.—Recent Investigations.—In last year's report a reference was made to investigations, carried out in the early part of 1905 by Dr. F. Gotschlich at the pilgrim

quarantine camp at Tor, relating to the finding of vibrios in the intestines of 38 pilgrims (107 cadavers examined) who had died from dysentery and other forms of colitis while on their return journey from the Hejaz. Six of the 38 vibrio strains were found by Gotschlich to be identical with the vibrio of true Asiatic cholera not only culturally and morphologically but also according to the agglutination and Pfeiffer reactions; and yet (1) there was no evidence, clinical or pathological, that the pilgrims from whose intestines these six vibrio strains were isolated had ever suffered from cholera, and (2) no case of cholera was known among the pilgrims visiting Mecca during that season, so these six pilgrims had not infected others. Gotschlich regarded the six pilgrims, who all came from regions in which cholera is reputedly endemic, as cholera vibrio "carriers" and stated that the absence of an outbreak of cholera among the pilgrims might possibly have been due to the vibrios being (*a*) eliminated only in small numbers and (*b*) perhaps of low virulence. The other 32 strains were isolated from the intestines of pilgrims of diverse nations and were easily distinguished from Koch's cholera vibrio; they were in all probability derived from the drinking water—in the water of the holy well in the Kaaba at Mecca saprophytic vibrios were found. It is interesting to note that during the pilgrim season 1905-6 there was again a complete absence of cholera among the returning pilgrims but in two cases a vibrio identical with the above six strains was isolated at the Tor quarantine camp. Gotschlich examined the fæces of 127 pilgrims in hospital for various diseases and found vibrios in 18. No reaction with cholera serum (obtained from Berlin) was given by 16 of these 18 strains even in a dilution of 1 in 50, while the specific reaction in a dilution of 1 in 2,000 was given by the other two. The Tor vibrios have occasioned a great deal of work with the object of ascertaining whether they are real cholera germs or not. The matter is not yet settled.

Cholera in Bengal.—In Bengal in 1905 the total number of deaths recorded as due to cholera was 146,339 or 2·93 per mille of the population as compared with 81,463 or 1·63 per mille in 1904, and 138,577 or 2·77 per mille—the average figures for the five years 1900-4. The mortality during 1905 was higher than in any of the previous eight years except 1900. No district was entirely free from the disease which attacked 18,652 villages and assumed an epidemic form in 104 registering circles, as compared with 14,241 villages, and 45 registering circles in 1904. The district of Gaya in the Patna division suffered most severely and lost from this cause 6·63 per mille of its population. Other districts in which a high mortality from cholera was recorded were Purnea (5·17 per mille), Patna (5·0 per mille), Shahabad (4·94 per mille), Howrah (4·78 per mille), Bhagalpur (4·74 per mille), and Puri (3·97 per mille). Ranchi and Palamau, which remained free from this disease in 1904, were the least affected of all the districts during the year. Compared with the previous year, the mortality from this cause was smaller in only eight districts, the most important of these being Singhbhum, Darjeeling, Hazaribagh, and Manbhum. The great prevalence of the disease in Gaya is said to have been due to the contamination of the wells by surface washings in consequence of a very heavy continuous rainfall directly after excessively dry weather. Considering the province as a whole, the incidence was greatest during the last four months of the year and least during May and June.

The highest death-rates for cholera recorded in towns were 12·94 per mille in Gaya, 11·99 in Puri, 11·54 in Buxar, 11·49 in Tikari, and 10·10 in Chapra. Among rural areas, the highest rates were recorded in Kadwa (16·23 per mille) and Kasba Amur (14·89 per mille), both in Purnea.

In the district of Gaya over 6,900 wells were disinfected with permanganate of potash, and the disease is said to have been thus kept in check. This method of purifying well-water was also applied in 16 other districts; from Champaran the statement comes that good results followed its use.

Among the European seamen of the port of Calcutta there was only one death from cholera: there were 33 among the native floating population.

Cholera in Eastern Bengal and Assam.—The number of deaths attributed to cholera in the new province of Eastern Bengal and Assam during 1905 was 142,312, equal to a ratio of 4·77 per 1,000 of the census population. The average death-rate for cholera during the decade 1895-1904 for the combined districts which now constitute the province of Eastern Bengal and Assam was 2·30 per mille, which is less

than half the mortality during the year under review. The provincial sanitary commissioner remarks that in some cases there was a history of the disease spreading from village to village along the course of the streams and rivers, especially where the people relied on the river water for household purposes. From October to December the disease raged in most of the districts bordering on the lower reaches of the Brahmaputra and Ganges; the districts of Mymensingh (10·5 per mille), Kamrup, Goalpara, Bogra, and Pabna, all returned death-rates above 7 per mille: in these five districts during the last three months of the year the epidemic was sufficiently severe to interfere with business. In some places the villagers were unable to dispose of their dead in the ordinary way and either threw the bodies into the rivers to be carried away by the flood or left them to rot on the surface of the ground. On the other hand, districts on the upper reaches of the Brahmaputra and districts having little or no connection with the great water-ways suffered only to a small extent. In Mymensingh, which suffered most severely during the year, the decennial rate was only 2·18 per mille; Kamrup is the district which showed the highest decennial death-rate (5 per mille). In Dacca, wells and tanks in the affected localities were subjected to the permanganate of potash treatment, and it is reported that the disease was brought under control almost immediately after this treatment was begun.

The towns which recorded death-rates over 10 per mille were Tangail, Sherpur, Sibsagar, and Bogra: the quinquennial death-rate for cholera in Tangail is 13·8 per mille of the population, while the quinquennial rate for no other town in the province is over 4 per mille.

The death-rate (2·14 per mille) from cholera among tea-garden coolies was much less than that among the general population of the province, the highest coolie death-rate being 2·69, recorded in the Sylhet district. Other districts returning rates over 2 per mille were Cachar, Kamrup, and Lakhimpur. Altogether there were reported 391 cases, of which 252 occurred in the Karimganj Sub-division.

Cholera in the United Provinces.—The total number of deaths from cholera recorded in the United Provinces during 1905 was 121,790, equal to a ratio of 2·55 per 1,000 of population, as compared with a total of 6,617 and a ratio of ·14 during 1904. The average death-rate of the preceding quinquennium was ·92 per mille. Of the 48 districts no death from cholera was reported during the year in six, and not more than nine deaths in any of ten other districts. The districts where the mortality from this cause was highest were Sultanpur (25·30 per mille), Partabgarh (12·14), Fyzabad (10·63), Rai Bareli (10·55), Bara Banki (8·44), and Basti (6·85); of these six districts, the first three mentioned and Bara Banki are in the Fyzabad division.

The highest death-rates for this disease recorded in towns were 13·48 per mille at Jais (Rai Bareli), 13·32 at Radauli (Bara Banki), 10·75 at Ramnagar (Benares), 9·55 at Barhaj (Gorakhpur), 6·42 at Azamgarh, and 6·29 at Sandila (Hardoi). Of the 107 towns with populations of 10,000 or more, 61 did not return any death from this cause.

No case of cholera was reported to have occurred at the Dikhauti and Mahavaruni fairs at Hardwar, the Garhmuktesar fair at Meerut, the Batesar fair at Agra and the *Magh mela* at Allahabad. During the time of the Dadri fair at Ballia, cholera was present in Ballia and the neighbouring districts, yet only 56 cases with 45 deaths occurred among the multitude, numbering about 700,000, that attended this festival on the principal bathing day.

Cholera in the Punjab.—In the Punjab cholera did not assume a severe epidemic form during the year. The total number of deaths was 2,197, yielding a ratio of ·11 per mille of population as against ·04 in the previous year and ·41—the average of the quinquennial period ending with 1904. The largest number of deaths amounting to 1,624 or three-quarters of the total registered in the province occurred in the district of Lahore, Multan coming next with only 141 deaths. No death from cholera was reported to have occurred in the province during the first four months of the year, and only 13 and 36 deaths were recorded in May and June, respectively; but the number of deaths registered in July, August, and September amounted to 87 per cent. of the total number of deaths from cholera during the year in the province. Of the 145 municipal towns in this province, cholera was reported from only 26; the highest death-rates recorded in towns were 13·78 per

mille of the population in Shujabad (Multan), 6·11 in Sangla (Gujranwala), 4·13 in Chunian, 2·86 in Kasur, 1·95 in Lahore, and 1·81 in Khem Karn (the last four towns are in Lahore district).

On the appearance of cholera in any locality, the sources of drinking water open to contamination were disinfected with permanganate of potash.

Cholera in the North-West Frontier Province.—In 1904 the North-West Frontier Province was practically free from cholera, only one death having been reported from a village in the Hazara district; in 1905 in the same district the disease prevailed in epidemic form during September and October, 415 cases with 303 deaths having been registered. Evidence seems to point to infection having been conveyed to a village in this district by a man who had come from Lahore, where the disease was at the time prevalent; from this village infection rapidly spread to neighbouring villages and towns. The civil surgeon reported that "the people were generally apathetic and, in some cases hostile" to the prophylactic measures adopted. There was not a single death from cholera during the year in any other district in the province.

Cholera in the Central Provinces and Berar.—In the Central Provinces and Berar the total number of deaths recorded in 1905 as due to cholera was 1,217, or ·10 per mille of the population, as compared with a total of 2,967 and a ratio of ·24 in 1904. During 1905 the disease was confined to the districts of Bilaspur (605 deaths), Raipur (382 deaths), Jubbulpore (136 deaths), Narsinghpur (60 deaths), Wardha (23 deaths) and Chanda (10 deaths). The disease is said to have been introduced by infected pilgrims returning from Puri (Jagannath). The highest district death-rates were ·55 in Bilaspur, ·26 in Jubbulpore, and ·25 in Raipur.

With the exception of one doubtful case reported from Yeotmal, there was no cholera in the Berar districts during the year.

Cholera in the Madras Presidency.—In the Madras Presidency in 1905 there were 16,888 deaths recorded as due to cholera, giving a ratio of ·5 per mille of population, as compared with a total of 23,109 and a ratio of ·6 per mille in 1904. The ratio for the year under review is the lowest since 1895. The disease was reported from all the districts of the presidency except the Nilgiris, Tinnevelly and Coimbatore (the last mentioned registered one case). The highest death-rates recorded in districts were 7·2 per mille in Madras, 2·8 in Bellary, 1·8 in Chingleput, 1·3 in Nellore, 1·2 in Kistna, and 1·1 in Godaveri.

The highest death-rates for cholera recorded in towns were 16·1 in Pulicat (Chingleput), 7·7 in Kampli (Bellary), 7·2 in Madras, 6·8 in Bezwada (Kistna), 6·0 in Dowlaishweran (Godaveri) and 6·6 in Nellore. In Madras the disease broke out in a severe form about the beginning of the latter half of the year and accounted for 3,534 deaths. The cause of the outbreak was supposed to be due to the use of "polluted sources of water-supply when the Red Hills' supply ran short of requirements."

Water-disinfection by permanganate of potash was, as usual, carried out in the areas invaded by cholera and was found to yield good results.

Cholera in Coorg.—During 1905 no death from cholera was recorded in Coorg. This small province has been free from the disease since 1901, in which year 58 deaths from this cause were reported.

Cholera in the Bombay Presidency.—In the Bombay Presidency there were recorded during 1905 as due to cholera 5,396 deaths, equal to a ratio of ·29 per mille of population, as compared with 13,156 deaths or a ratio of ·71 per mille in 1904. The disease was practically confined to the southern registration district, where 5,318 deaths, *i.e.*, 98·55 per cent. of the total number of deaths in the presidency, were recorded. The highest death-rates for this disease recorded in districts were 2·02 per mille of population in Bijapur, 1·91 in Dharwar, and 1·60 in Belgaum; outside these districts the incidence of cholera was very slight, Sind and Gujarat, with the exception of one doubtful case reported from Ahmedabad district, remaining free from the disease throughout the year.

Deaths from cholera were recorded in 11 of the 56 town-circles in the presidency as compared with 25 town-circles in 1904, the highest rates being 6·26 in Gadag-Bettigeri (192 deaths), 4·71 in Bijapur (112 deaths), 4·46 in Gokak (44 deaths), 2·79 in Kalyan (30 deaths), and 1·70 in Dharwar (52 deaths).

The acting deputy sanitary commissioner reported in connection with the epidemic in the southern registration district: "During the year cholera has attacked most severely the towns and villages on the banks of rivers and streams. This probably has relation to density of population and to favourable conditions of soil (porosity and moisture) as well as to the rivers or streams acting in the dual capacity of sewers and sources of drinking-water."

Cholera in Burma.—In Lower Burma during 1905 there were recorded as due to cholera 3,511 deaths, equal to a ratio of ·63 per mille of population, as compared with 2,472 deaths or ·45 per mille for the same cause in 1904. The highest death-rates recorded in districts were 4·11 per mille of population in Mergui (365 deaths), 1·61 in Kyaukpyu (272 deaths), 1·58 in Tharrawaddy (624 deaths), and 1·19 in Maubin (337 deaths); in towns the highest death-rates were 8·98 in Minhla, 6·16 in Letpadan, 5·41 in Kyaukpyu, and 5·02 in Kyaiklat.

In Upper Burma the total number of deaths recorded during 1905 as due to cholera was 1,836 as compared with 508 during 1904. The disease prevailed in every district except one—Yamethin; the highest mortality was recorded in Myingyan (1·59) and Pakokku (1·14), where 567 and 343 deaths, respectively, occurred. The highest death-rates recorded in towns were 9·10 in Pakokku, 6·23 in Minbu, 5·89 in Myingyan, and 5·46 in Monywa.

The provincial sanitary commissioner reports that in Lower Burma there was a decline of incidence during the heaviest part of the monsoon, namely, June, July, and August; whereas in Upper Burma the prevalence of the disease increased throughout the monsoon months. He expresses the opinion that the heavy rainfall of Lower Burma served to dilute, if not completely change contaminated water sources, while in Upper Burma the relatively small rainfall served to scatter the cholera virus without causing effective dilution or flushing of water sources by storm water.

Cholera in Ajmer-Merwara.—During 1905 no death from cholera was recorded in Ajmer-Merwara. This small province has now been free from the disease for three years in succession; 32 deaths were reported in 1902.

Small-pox.—From the statement in the first paragraph of this section it will be seen that in British territory in India the death-rate per 1,000 of population on account of small-pox rose from ·24 in 1904 to ·31 in 1905, the latter ratio, however, being lower than that of any of the three years 1901 to 1903. The mean ratio for the quinquennial period ending 1904 was ·40 per mille. The total number of deaths from this disease recorded during 1905 was 70,962 against 55,232 in 1904, and 93,693 in 1903. In all provinces except the Bombay Presidency and Lower Burma, the death-rates during 1905 were lower than the corresponding means of the quinquennium 1900-4; the greatest falls in the death-rates were recorded in Ajmer-Merwara, the North-West Frontier Province and Bengal. As compared with 1904, a year in which the incidence was exceptionally low, the death-rate during 1905 showed an increase in all provinces, except Bengal, Eastern Bengal and Assam, the United Provinces, Punjab, and the North-West Frontier Province—the increase being greatest in Lower Burma and the Bombay Presidency. The small-pox mortality in towns was nearly three times as heavy as that in rural areas; and the deaths of children under ten years of age amounted to 72·52 per cent. of the total number of deaths from this disease (in Burma alone was this percentage under 50).

In Bengal the number of deaths from small-pox fell from 11,090 (·22 per mille) in 1904 to 7,213 (·14 per mille) in 1905; the mean death ratio during the quinquennial period ending 1904 was ·54 per mille. As compared with 1904, the incidence of the disease was lower in 24 districts and higher in seven; Puri and Murshidabad were the districts most affected. The civil surgeon of Puri attributes the great prevalence of small-pox in that district to the backward uneducated state of the people; the civil surgeon of Murshidabad states that most deaths from this cause occurred in villages largely inhabited by Ferazi Muhammadans, who have for years resisted all attempts at vaccination. Only one town—Kishanganj in Purnea—suffered severely from this disease.

In Eastern Bengal and Assam during 1905, small-pox was the cause of 4,723 deaths, yielding a death-rate of ·15 per mille of population as compared with ·26 in 1904 and ·27—the mean ratio for the quinquennium ending 1904. The highest

rates in districts were 2·78 per mille in Kamrup and 1·11 per mille in Darrang. In the former district the disease occurred chiefly among the Mahapurushiyas who do not, for religious reasons, accept vaccination. In the town of Barpeta, the headquarters of this sect, the death-rate recorded was 3·54 per mille.

In the United Provinces 3,273 deaths were attributed to small-pox in 1905 as compared with 6,998 in 1904 and 21,950 in 1903, the corresponding rates being ·07, ·15, and ·46 per mille. The average rate for the quinquennial period 1900-4 was ·15. Eight districts were practically free from the disease during the year: the highest death-rate in districts was 1·44 per mille, recorded in Jhansi. Out of 107 towns having a population of 10,000 and upwards, only 33 furnished deaths from this cause and in none of them except Benares (where the rate was ·61 per mille) did the number of deaths exceed ten.

In the Punjab there were reported during 1905 as due to small-pox 4,723 deaths, equal to a ratio of ·23 per 1,000 as compared with 9,624 deaths and a ratio of ·48 per 1,000 in 1904. The average death-rate during the quinquennial period ending 1904 was ·52 per mille. The highest rates in districts were ·89 per mille in Ludhiana (598 deaths), ·76 in Ferozepore (708 deaths), ·68 in Lahore (783 deaths) and ·55 in Montgomery (268 deaths). The rate was only ·01 per mille in the three districts—Kangra (nine deaths), Jhang (six deaths) and Attock (five deaths). The highest death-rates in towns were recorded in Ludhiana (9·09 per mille) and Pakpattan (5·17 per mille). The municipal committee of Ludhiana has resolved to introduce the Vaccination Act into their town; the towns in which the Act was in force recorded a death-rate of ·36 as compared with a rate of ·82 in towns where vaccination was not compulsory.

In the North-West Frontier Province the number of deaths from small-pox fell from 2,694 in 1903 and 1,561 in 1904 to 571 in 1905, the ratios being 1·35, ·78, and ·29 per mille, respectively. Out of the 571 deaths no less than 374 occurred in the district of Hazara and 182 in that of Peshawar; no death from this disease was recorded in the district of Bannu. In the three towns Bannu, Kohat, and Dera Ismail Khan, in which the Vaccination Act was in force, there was very little small-pox.

In the Central Provinces and Berar there were recorded, during the year, 8,364 deaths from small-pox against 2,026 in 1904. The increase is attributed by the provincial sanitary commissioner to less vaccination during recent years owing to the presence of plague. The largest number of deaths were reported in the Buldana (1,483), Nagpur (1,398), and Saugor (1,114) districts. It is, however, suspected that many deaths from this disease were concealed or returned as chicken-pox or measles.

In the Madras Presidency small-pox accounted for 18,540 deaths against 9,891 in 1904. Cases were reported from all the districts in the presidency, but the fatality from this disease was greatest in Madura and Bellary, in each of which a rate of 1·5 per mille was recorded. Of the 61 municipal towns of this presidency, 23 enjoyed immunity; the remaining 38 returned 2,709 deaths, the highest rate being 8·0 per mille in Dindigul. The provincial sanitary commissioner urges compulsory vaccination in rural areas.

In the Bombay Presidency the number of deaths from small-pox recorded in 1905 was 16,985 (·92 per mille) as compared with 4,289 (·23 per mille) in 1904. The mean ratio for the quinquennial period ending 1904 was ·26 per mille, which is ·66 per mille less than the rate for the year under review. The mortality during 1905 was the highest recorded during the past 27 years. The disease was prevalent in every district and deaths were reported from 226 registering circles out of a total of 287. The districts of Khandesh and Bombay contributed 7,694 and 2,148 deaths, respectively, the two combined thus accounting for much more than half the total number of deaths in the presidency; the death-rates in this districts were 5·39 and 2·82 per mille, respectively. A notable feature was the high mortality among children under one year of age, amounting to nearly 36 per cent. of the total number of deaths.

In Burma there was a considerable increase of prevalence of small-pox during the year, the total number of deaths being 6,161 against 1,809 in 1904. Lower Burma was chiefly affected, its death-rate being 1·01 per mille of the census population as compared with ·24 in 1904 and a mean of ·36 for the quinquennium ending 1904. In Upper Burma the increase was very slight, namely, ·18 against ·17 in 1904: it should be noted, however, that the mean in Upper Burma for the preceding

quinquennium was ·41, which is more than twice as high as the rate for 1905. In Rangoon and in the Pyapon and Hanthawaddy districts, all in Lower Burma, the heavy rates of 2·98, 2·79, and 2·32 per mille, respectively, were recorded.

In Ajmer-Merwara 277 deaths (·58 per mille) from small-pox were recorded during 1905 as compared with 129 (·27 per mille) in 1904. In Coorg the number of deaths reported as due to this disease was 132 against 16 in the previous year.

Plague.—The number of deaths recorded as due to plague in the Indian Empire in 1905 was 1,069,140, compared with 1,143,933 in the previous year. In the British provinces there was a slight increase, the registered deaths numbering 940,821 or 2,811 more than in 1904; but there was a remarkable change in the course of the epidemic. In each of the first five months of 1905, the number of deaths was considerably greater than in the corresponding months of 1904, but from June onwards this relation was reversed, and the number of deaths in the last seven months of 1905 was 69,845, or little more than one-fourth of the number, 263,789, recorded in the last seven months of 1904. In the Native States the registered plague deaths totalled 128,319 against 205,983 in the previous year; in every month there was a decrease as compared with 1904, but the decline was most remarkable in the last seven months of the year. As in 1904, the maximum incidence of the disease occurred in April, and, for the fourth year in succession, the minimum was recorded in July.

As we have seen, the year 1905, apart from plague, was exceptionally unhealthy, but the deaths from plague in British territory numbered more than one-fifth of the total deaths recorded under the heading fevers, were more than twice as numerous as the exceptionally large number of deaths ascribed to cholera, and were three and a half times as numerous as the deaths from dysentery and diarrhœa. The mean plague death-rate in the British provinces was 4·17 per thousand; females suffered far more than males, the death-rates of the sexes being 3·83 and 4·52 per thousand, respectively, of the census populations of males and females. Although the numbers of deaths in Eastern Bengal and Assam and in the North-West Frontier Province were trifling, no British province, except Coorg, was altogether free from the disease, and no Native State escaped, except those in Madras, the Central Provinces, and Baluchistan. In each of the Presidency towns the number of deaths rose; the totals in 1905 were, in Calcutta, 7,372; in Madras, 22; and in Bombay, 14,171; against 4,689, 8, and 13,504, respectively, in 1904; and in Rangoon where the disease appeared for the first time in epidemic form in February, 1905, there were 2,468 deaths.

In last year's report an account was given of the epidemiology of plague in India founded upon the evidence contained in the numerous official reports on the disease, and upon special reports contributed by most of the experienced observers in this country. There is no new fact of importance from the point of view of general epidemiology to add this year, but the conclusions and speculations based upon statistical data are now being justified or modified by the precise methods of the laboratory.

We saw that an Advisory Committee representing the India Office, the Royal Society, and the Lister Institute had been established, and that a Commission to work in India under their direction at the problems of the etiology of plague, had been appointed. It is now some eighteen months since the working Commission began their labours and the Advisory Committee have recently issued reports of some of the results achieved which bid fair to overshadow in importance all recent experimental work of a similar kind.

On the departure from India of Dr. Martin in October, 1905, Major Lamb assumed direction of the working Committee which consisted of the following members:—

Major George Lamb, Indian Medical Service.
Captain W. Glen Liston, Indian Medical Service.
Dr. G. F. Petrie, Assistant Bacteriologist, Lister Institute.
Mr. S. Rowland, M.A., &c., Assistant Bacteriologist, Lister Institute.
Captain T. H. Gloster, Indian Medical Service.
Assistant Surgeon M. Kasava Pai, M.B., C.M., Madras.
Mr. V. L. Manker, L.R.C.P., L.R.C.S., D.P.H.
Hospital Assistant, Ramachandier, Mysore.
Hospital Assistant C. R. Avari, Bombay.

In order adequately to estimate the importance of the work done by the Commission it would be necessary to form a clear conception of the ideas current a year

ago regarding the causation of the spread of plague. It is, however, impossible to do this for the opinion of well qualified observers varied greatly. It may be said that it was generally accepted that in bubonic plague disinfection was of little value—with all that this implies—and that it was widely believed that the rat was in some way the important factor in the spread of the disease. How it was spread by the rat was not understood, and although the theory of transference by fleas was well known, the flea was not believed to be the principal, or even a common agent; and many of the best observers would have been found ready to agree with Dr. Klein that, while it was possible for a flea that had just sucked from a rat blood well charged with *B. pestis*, by biting, to inoculate another rat, such an occurrence was not under natural conditions likely to occur. At the Plague Research Laboratory, where Captain Liston was working, ideas were much more advanced. It had been found that the common flea on rats in India,—provisionally named *P. pallidus* until identified by the Honourable C. N. Rothschild as *P. cheopis*—was very like *P. irritans*, and that, when deprived of its natural host, it would bite other animals. Captain Liston had made the discovery that guinea-pigs could be used as "traps" for rat fleas in plague-infected houses—a discovery of which it is impossible to overestimate the importance—and he had found that some of the fleas caught in this way had in their stomachs large numbers of plague germs which so far from being destroyed by the digestive juices, appeared to be multiplying. Many of the guinea-pigs on which such fleas were found died of plague. It had been shown that healthy animals could live beside plague-sick animals, and not contract the disease, and while there was no doubt that it was possible to communicate plague by way of the alimentary canal, it had been found that rats could eat small quantities of contaminated food without suffering any ill effects. It had been ascertained also that plague germs soon die in earth taken from the floors of Bombay houses. Attempts had been made to communicate the disease by means of fleas transferred to a healthy animal after feeding on a plague-sick animal, but these attempts had not been successful, owing, no doubt, to the germs in the blood of the plague-sick animal not being sufficiently numerous to infect the fleas.

One result of these experiments was the creation in the laboratory of a staff accustomed to handle and dissect rats, which greatly facilitated the development of the excellent arrangements which, with the freely given aid of the Bombay Municipal authorities, the Commission succeeded in organising for the purposes of their enquiry.

Transfer of Plague from Rat to Rat.—The Commission found* that if, in the presence of the rat flea, a healthy rat was confined in close proximity to a plague-infected rat, but in such a way as to preclude the possibility of contact with its body and excreta, the healthy rat frequently became infected. In cases where the healthy rat became infected, the infection must have been carried by the air or by fleas. In order to exclude aerial infection, attempts were made to conduct similar experiments in the absence of fleas; but, as it was found impossible to ensure the absence of fleas, experiments were made to ascertain whether plague could be transferred by fleas taken from rats in the septicæmic stage of plague to healthy rats. In 21 out of 38 experiments, healthy rats living in flea-proof cages, contracted plague after fleas taken from rats dying or dead of septicæmic plague had been placed on them.

Effects of Structure and of Light.—A series of experiments were conducted in specially constructed godowns which had been designed by Lieutenant-Colonel Bannerman and Captain Liston. There were in all six of these godowns, and the essential differences between them were the structure of the roof and the amount of light admitted. Two of the godowns were roofed with country tiles which afford good shelter for rats; two with Mangalore tiles, which afford little shelter for rats; and two with corrugated iron, where rats could not penetrate. In one of country tile roofs and in one of the Mangalore tile roofs there was a sky light. It was found that rat fleas were more abundant in the godowns roofed with country tiles than in the godowns roofed with Mangalore tiles, and that in both sets of godowns the number of fleas was far greater in the absence of light. In the godowns roofed with corrugated iron, only a few fleas were found which may have been introduced on the guinea-pigs used in the experiments.

Experimental Epidemics.—These godowns were used for a series of experiments in which a large number of healthy guinea-pigs were kept in confinement along with

* *Vide* "Journal of Hygiene," No. 4, Vol. 6, September, 1906.

a number of others infected with plague. It was found that epidemic plague did not occur when healthy guinea-pigs lived in close contact with plague-infected guinea-pigs if the access of fleas was prevented; but, in exactly similar conditions, if fleas were present in considerable numbers, plague spread among the healthy animals.

Fleas taken from guinea-pigs dying with plague started an "epidemic" among healthy guinea-pigs living in an uninfected godown, and this "epidemic" was maintained by the addition, from time to time, of other fleas.

It was found that when an "epidemic" has occurred among a number of guinea-pigs the contagion remains in the place of their confinement, and is effective in proportion as test animals introduced into it are accessible to and found infested with fleas, and that animals in a cage suspended two feet from the floor escaped the disease, while animals in a cage suspended two inches from the ground were infected.

Conditions in Plague-infected Houses.—Among the most interesting and valuable experiments performed by the Commission were those in which guinea-pigs were introduced into plague-infected houses. The following is a summary of, and conclusions drawn from, these experiments:—

"(1) Guinea-pigs allowed to run free in plague houses in many instances attracted a large number of fleas, which fleas were mostly rat fleas. A certain percentage (29) of these animals contracted plague, and died from the disease. The position of the bubo in the great majority of these cases was cervical.

"(2) If a plague house had been previously disinfected by the ordinary means of disinfection, fleas were still caught in large numbers on guinea-pigs set free in them. Further, a considerable number (29 per cent.) of these animals died of plague. The bubo in the great majority of these cases was again in the cervical region.

"(3) Fleas transferred from plague-infected rats found dead or dying in houses, were able to transmit plague to healthy animals in flea-proof cages in the laboratory. The bubo in all cases was in the cervical region.

"(4) Fleas transferred from guinea-pigs and other animals which had been placed for a few hours in plague houses, were able to transmit the disease to fresh animals when fed on these in flea-proof cages in the laboratory. The situation of the bubo in these animals was in the great majority of cases in the cervical region.

"(5) Animals were placed in plague houses in pairs, both protected from soil and contact infection, and both equally exposed to aerial infection, but one protected from fleas by means of a fine metallic curtain, and the other not so protected. None of the protected animals contracted plague while several of the unprotected animals died of the disease. The position of the bubo in every instance was in the cervical region.

"(6) Animals were placed in plague houses in pairs, both protected from soil and contact infection, and both equally exposed to aerial infection, but one surrounded with a layer of 'tangle-foot'* and the other surrounded with a layer of sand. The following observations were made:—

(*a*) Many fleas were caught on the tangle-foot, a certain proportion of which were found on dissection to contain in their stomachs abundant bacilli microscopically identical with plague bacilli. Out of 85 human fleas dissected only one contained these bacilli, while out of 77 rat fleas 23 were found thus infected.

(*b*) The animals surrounded with tangle-foot in no instance developed plague, while several (24 per cent.) of the non-protected animals died of the disease."

The Effect of Passage on the Virulence of B. pestis.—A contribution was made to the vexed question of the effect upon the virulence of *B. pestis* produced by repeated passage through the rat. Twenty-six passages occupying 89 days were effected by subcutaneous injection, but while there was evidence of varying susceptibility to plague among the rats of Bombay, there was no evidence of alteration in the virulence of *B. pestis*. A similar series of passages were made by cutaneous inoculation; no change in the virulence of the bacillus resulted, but it was found that a large percentage of Bombay rats were immune to infection in this way. Comparison with the records of experiments made at the Plague Laboratory in 1904 showed there has been no increase in immunity of the Bombay rats in the last two years.

---

* A sticky fly-paper.

Duration of Infection in Floors.—A series of important experiments were conducted for the purpose of determining how long infection persists in floors which have been contaminated with cultures of plague bacilli. It was found that floors of cowdung retain infection for 48 hours; but floors of *chunam* do not retain it for 24 hours, infectivity being tested in both cases by cutaneous inoculation. Testing infectivity by allowing susceptible animals to run freely about on the floors, it was found that while cowdung floors retained infectivity for 12, but less than 24, hours, *chunam* floors retained it for six but less than 12 hours.

Bacilli in Blood, Urine, and Fœces of Rats.—The following is a summary of the results of the experiments made. The blood of plague-infected rats may contain an enormous number of plague bacilli, even as many as 100,000,000 per c.c. having been found before death. On the other hand, rats occasionally die from plague with little or no septicæmia. An insect sucking the blood of most rats shortly before death would imbibe a large number of bacilli.

While the blood of a rat may have as many as 100,000,000 organisms in a c.c., the urine may have none at all, or at least less than 10 per c.c. Plague bacilli were discovered in the urine in 29 per cent. of the cases. When the urine does contain plague bacilli they are always present in much fewer numbers than in the blood.

The fæces of rats dead of plague and the blood of which contained abundant bacteria, are not highly infective, and would appear to play little part in the spreading of the epizootic.

Human Plague Septicæmia.—The blood of 28 persons suffering from plague was examined. In 12 cases no bacilli were discovered, the 12 including all those (five) that ended in recovery. It was found that plague septicæmia may be irregular in type, and that it may occur at a comparatively early stage of the disease. It appears that microscopical examination of the blood is not a trustworthy method of determining the degree of septicæmia.

Chronic Plague in Rats.—Chronic plague was found to exist among rats in a village in the Punjab during the absence of acute plague. The affected animals were not emaciated, and did not appear to suffer in any way. It is of importance, because it suggests infection by food, that the bubo in each case was within the abdomen.

Varieties of Rat Fleas.—An interesting note by the Honourable C. N. Rothschild shows that in Great Britain and Northern Europe the common flea on rats (*M. decumanus*, and probably *M. rattus* also), is *Ceratophyllus fasciatus*; but in India, and probably throughout the old world the common rat flea is *P. cheopis*.

Inoculation.—The Director of the Parel Laboratory, Bombay, reports that the demands for prophylactic vaccine during 1905 were more than double those of 1904. The opinions of those who have had considerable experience in the use of this fluid, as prepared at the Parel Laboratory, are that (1) the state of health remained unimpaired after inoculation, even in cases where the inoculated were children of poor constitution; (2) the vaccine had a marked prophylactic effect; (3) immunity lasted for a period ranging from 6 to 12 months or more; and (4) no untoward results had occurred except, very rarely, an abscess at the site of inoculation due to neglect of antiseptic precautions on the part of the operator. According to some the severity of the attack among those of the inoculated who did happen to get plague was greatly diminished, the type of the disease among the inoculated being milder, and the case-mortality consequently lower, than among the non-inoculated. Before the onset of the last plague epidemic in Bombay City, the Health Officer induced a large number of the municipal labourers to submit to inoculation, and the following statistics, showing the results of this operation, are of exceptional value as the inoculated and non-inoculated were equally exposed to infection, and so under strictly comparable conditions. During the plague season the number of municipal employés inoculated was 7,182, the number remaining non-inoculated being 418. The following statement gives a tabular view of the results; if the inoculated had

——	Strength.	Attacked.	Died.	Percentage.	
				Attacked.	Died.
Inoculated	7,182	14	13	·19	·18
Non-inoculated ...	418	28	26	6·7	6·2

suffered to the same extent as the non-inoculated, they would have furnished 481 attacks, and 446 deaths, instead of 14 and 13, respectively. It will be noted that the case-mortality, in this instance, is identical (92·85 per cent.) among inoculated and non-inoculated; there can, however, be no doubt about the prophylactic value of the vaccine, and it is certain that inoculation is a most efficient measure in dealing with epidemics of plague. On the appearance of an outbreak, as we have no effectual means at present of destroying rats and their fleas, the people must vacate infected houses (*i.e.*, go away from the infected rats and their fleas), or submit to inoculation (*i.e.*, be protected against the disease), or, better still, combine the advantages of evacuation and inoculation. If evacuation is impossible, inoculation is indispensable.

The Destruction of Rats.—The relation of rat plague to human plague, and the connection that rats and rat fleas have with the spread of human plague have already been discussed. It is obvious that every infected rat destroyed means the removal of a source of infection, and, consequently, the destruction of infected rats cannot fail to have a beneficial effect on plague epidemics. In Bombay and elsewhere, leaflets on the advisability of killing rats have been distributed freely amongst the people. Various methods of killing rats have been tried, but the two which have won most favour are (1) the "wonder" rat trap, and (2) the proprietary poison known as the "common sense exterminator." *Danysz' virus* has had an extensive trial in several provinces, but the results have not been satisfactory. During the last plague season an experiment was conducted in the Punjab to test the efficacy of rat destruction as an anti-plague measure. A tract of country, about 70 or 80 square miles in area, was mapped off in the Delhi district, and in this area rat killing was carried out systematically and energetically. The experiment, however, failed to show any marked contrast between the plague incidence in the area selected for rat destruction, and in other areas of the district for two reasons, namely, (1) the whole Delhi-Gurgaon district escaped with very little plague during that particular season; and (2) in consequence of the popularity of the measure with the people a considerable amount of rat destruction was carried on in areas adjoining the experimental one. No definite conclusion could, therefore, be drawn from this particular experiment, but "the evidence so far as it goes is favourable to rat destruction as an anti-plague measure." One important point was brought out by the results of this experiment—the difficulty, apparently the impossibility, of completely freeing a place from rats. In a large village (Fattehpur Biluch), which had suffered from plague in previous years, rat destruction was carried on extensively and zealously, yet "plague broke out, apparently from endemic infection, and was accompanied by *rat* mortality"; the only discernible effect, which could possibly be attributed to the destruction of rats was that the spread of the epidemic was extremely slow, and the incidence of the disease slight in this village compared with neighbouring villages in which rat destruction had not been attempted. In other districts, and in other provinces, rat killing was carried out on a large scale; the results are encouraging, but, as the incidence of plague during the past season was light in many untreated areas in the same districts and provinces, it would be fallacious to conclude that a decrease in prevalence of plague in treated areas was entirely due to rat destruction. The question which requires to be considered, and the answer to which will settle the degree of importance to be attached to rat destruction as an anti-plague measure is "how near an approach to absolute extermination of rats in a given area is practically possible?" If absolute extermination in an infected locality is impossible, it is evident that rat destruction will not guarantee the non-recrudescence or suppression of plague in that locality; all that can be expected from the measure is diminished severity of plague epidemics.

Plague in Bengal.—Plague raged with great virulence in Bengal during 1905, and carried off 126,084 persons against 75,433 in the previous year, the ratios being 2·52 (the highest on record in this province), and 1·51 per mille, respectively. The average number of deaths of the preceding quinquennium was only 58,225. As in previous years, a larger number of females (70,833) succumbed to this disease than males (55,251). Five districts out of 32 escaped entirely from plague. The highest death-rates in districts were 14·79 per mille in Saran, 14·72 in Patna, and 8·83 in Gaya. The civil surgeon of Patna states that the incidence was very heavy amongst the Muhammadan weavers who are fatalists, and do not generally vacate their houses when infected. As regards towns, the highest rates were 65·98 per mille in Daudnagar, 43·22 in Siwan, 29·59 in Revelganj, 29·51 in Tikari, and 28·79 in

Monghyr. The largest number of cases was reported in March, and the smallest in July. Rat destruction was carried on in many places but notably in the Giridih coal fields and in Bihar.

Plague in Eastern Bengal and Assam.—During 1905 only six deaths from plague were reported in Eastern Bengal and Assam; all the cases were imported. Campaigns against rats were carried on by means of the "common-sense exterminator" in the towns of Dhubri, Sylhet, and Silchar; the reports on the use of this poison were favourable.

Plague in the United Provinces.—In 1905 the number of plague deaths registered in the United Provinces was 383,802, equal to a ratio of 8·05 per mille (the highest on record in this province), as compared with 179,082 deaths, and a ratio of 3·75 per mille in 1904. The greatest number of deaths from this cause occurred in March, and the smallest in July. The districts which suffered most during the year were Muttra with a death-rate of 62·64 per mille, Ghazipur with 22·03, Allahabad with 19·94, Agra with 19·08, Ballia with 17·14, and Muzaffarnagar with 16·30. Only one district (Almora) was entirely free from the disease, but from Naini Tal only three cases were reported. Out of 107 towns having a population of 10,000 and upwards, only eight remained free from the disease throughout the year; the towns most affected were Kiratpur (Bijnor), with a death-rate of 71·82 per mille, Dibai (Bulandshahr) with 52·94, Hapur (Meerut) with 44·39, Brindaban (Muttra) with 41·51 and Ramnagar (Benares) with 41·17.

Plague in the Punjab.—The number of deaths attributed to plague in the British districts of the Punjab during 1905 was 334,897, giving a death-rate of 16·65 per mille of population; the epidemic was of considerably less severity than that of the previous year with its 396,357 deaths, and death-rate of 19·71 per mille. (The mortality, however, in the Native States of this province was much higher than in the previous year.) In each of nine districts over 20,000 people perished from this cause; Rohtak lost 31,952, Amritsar 29,931, Gurgaon 29,172, and Lahore 28,787. In ten districts the death-rates recorded were over 20 per mille of the population, the highest rates being 52·63 in Rohtak, 40·88 in Gurgaon, 34·21 in Ludhiana, 33·99 in Amritsar, and 29·69 in Lahore. The districts of Simla and Muzaffargarh remained entirely free from the disease during the year. The mean mortality in rural areas fell from 20·34 in 1904 to 17·22 in 1905, and that in towns from 14·09 to 11·63. None of the towns suffered very severely during the year, 8·39 in Jullundur, and 6·91 in Amritsar being among the highest rates. The month of greatest prevalence was April, May coming next; fewest cases occurred in September.

Plague in the North-West Frontier Province.—There were only three cases of plague in the North-West Frontier Province during 1905, all three having been imported from the Punjab. In each case all necessary precautions were taken to prevent the spread of the disease, with successful results. It is noteworthy that although cases of plague have been frequently imported into this province the disease has never, at least up to the close of 1905, gained a footing on the west side of the Indus.

Plague in the Central Provinces and Berar.—In 1905 there were 5,345 deaths from plague in the Central Provinces as compared with 32,820 in 1904. In two (Damoh and Narsinghpur) of the 19 districts, no death from this cause was reported, and in each of four others the number of deaths recorded was less than six. The districts which suffered most were Burhanpur (541 deaths) with a death-rate of 5·82 per mille, Jubbulpore (1,535 deaths) with a rate of 2·96, Chhindwara (913 deaths) with a rate of 2·24, and Balaghat (602 deaths) with a rate of 1·84.

In Berar the number of deaths from plague reported during the year was 7,361 against 10,046 in 1904. The highest death-rates in the districts were 5·92 in Buldana (3,632 deaths) and 4·51 in Akola (3,407 deaths); only one death was reported in the district of Yeotmal during the year.

The month of maximum plague fatality in these provinces taken together was October, March coming next; that of minimum fatality was July, in which only one death from this cause occurred; there was an exceptionally heavy incidence of plague in Akola in October. The proportion of males that succumbed to the disease was slightly greater than that of females. Various methods of destroying rats

were experimented with in these provinces during the year: the "common sense exterminator" was tried in a few places with satisfactory results; Danysz rat virus was also tested, but proved a failure.

Plague in Madras.—The number of deaths from plague reported in the Madras Presidency during 1905 was 5,788 as compared with 20,125 in the previous year. Most cases were recorded in January and fewest in June. Out of a total of 23 districts, no death from this cause was registered in seven, viz., Ganjam, Godavari, Guntur, Kistna, Nellore, Tinnevelly and Trichinopoly, and in six others only a few imported cases occurred. In the remaining ten districts the highest death-rates were 3·6 in Bellary and 1·9 in the Nilgiris. In Bellary and South Canara the disease was present throughout the year. As regards towns, plague was indigenous in Bellary, Adoni, Madras, Ootacamund, Coonoor, Tiruppatur and Mangalore. The destruction of rats was vigorously undertaken, the method which has largely found favour in many quarters being poisoning by the "common sense exterminator."

Plague in Bombay.—Plague was much less prevalent in the Bombay Presidency during 1905 than in the previous year, 71,363 deaths (37,790 males and 33,573 females) having been recorded against 223,957 in 1904. The death-rate fell from 12·12 per mille in 1904 to 3·86 per mille in 1905, the mortality during the year under review being thus less than one-third of that during the preceding year. Only in the two years 1897 and 1900, since the appearance of plague in India in 1896, was the number of deaths registered less than in 1905. This abatement of plague was shared by all the districts in the Presidency, except Ratnagiri and three districts (Larkhana, Sukkur, and Upper Sind Frontier) in Sind; in Bombay City, also, there was a slight increase. In Sind, Thar and Parkar was entirely free from plague and all the other districts, except Karachi, were only very slightly affected. The highest ratios recorded in districts were 11·68 in Satara, 6·53 in Karachi, 5·59 in Dharwar, and 5·40 in Belgaum; the rate in Bombay was 18·63. Out of a total of 63 towns, 52 (*i.e.*, 82·54 per cent.) were affected by plague, the highest rates being 38·41 per mille in Yeola (636 deaths), 24·86 in Karachi (2,807 deaths), 22·92 in Hubli (1,380 deaths) and 21·15 in Borsad (275 deaths). In November of 1904, a fall in the recorded plague mortality was noted, and from this date the mortality continued to fall steadily, with the exception of a slight rise in March, during the first half of 1905—reaching a minimum in June. From June to September the numbers of deaths gradually increased but fell steadily again from September till the end of the year; so that in December of 1905 only 2,459 deaths from plague were registered as compared with 17,105 in December of 1904, and 24,451 in December of 1903. Most cases were reported in January and fewest in June. Although the incidence of plague was so much lighter during the year, there appeared to be no diminution of the virulence of the disease; the average case-mortality was 75 per cent.

Plague in Burma.—Up to the end of 1904 the occurrence of plague in Burma was limited to imported cases, of which two terminated fatally in 1899, three in 1900, three in 1901, nine in 1903, and three in 1904. During 1905 there were 4,132 cases, and 3,692 deaths. The case-mortality is thus no less than 89 per cent., from which it may be suspected that many non-fatal cases were not reported, and helped to scatter about infective material. The first case that was certainly indigenous occurred in Rangoon in the third week of February, and many more cases were reported during the month. The outbreak originated in the Mussalman quarter of the town, where there were large grain stores; and, as all cases were not reported, and surveillance of contacts was impossible, infection spread rapidly within and beyond Rangoon. From the time of its recognition in February, plague has been present in this town throughout the year. In Lower Burma the mortality rose rapidly during March and April, continued high until July, and then steadily declined during the remaining months of the year: to a total of 3,045 deaths during the year, Rangoon alone contributed 2,468. In Upper Burma the heaviest incidence occurred in November and December, the total number of deaths recorded being 647—all of which, with the exception of one in April, were registered during the last six months of the year. The provincial sanitary commissioner states that meteorological conditions are apparently less in favour of the spread of the disease in Lower than in Upper Burma. The districts chiefly affected were Rangoon (9·79 per mille), Bassein (·43) and Toungoo (·38) in Lower Burma; and Meiktila (1·93) with 482 deaths, and Yamethin (·66), with 160 deaths in Upper Burma. No deaths

from this cause were reported from the Arakan division or the districts of Tavoy and Mergui in Lower Burma; or from the Minbu division or districts of Shwebo, Lower Chindwin, Kyaukse, and Myingyan in Upper Burma.

Plague in Coorg.—No death from plague was reported in Coorg until 1903, in which year 45 deaths were recorded. In 1904 the number of deaths from this disease was 25: in 1905, however, no death from this cause was registered.

Plague in Ajmer-Merwara.—The number of deaths from plague recorded in Ajmer-Merwara during 1905 was 2,480 against 158 in 1904. Most cases occurred in March, April, and May, when 665, 1,272, and 315 deaths, respectively, were registered, while in June no death from this cause was reported.

Fevers.—The total number of deaths recorded in British territory under the heading "fevers" during 1905 was 4,417,655, yielding a ratio of 19·57 per mille of population, as compared with a total of 4,093,981 and a ratio of 18·09 per mille in 1904. The death-rate returned under this heading in 1905 was higher than in any year since 1897, with the exception of 1900 and 1903. The year 1905 was in all respects more unhealthy than 1904, and it was to be expected that a large portion of the increased mortality during the year would be accounted for under this comprehensive heading. The largest number of deaths from fevers were, as usual, recorded in October, November, December, and January; there was also a slight, but very perceptible increase in the registered numbers of deaths under this heading in May and June; the lowest numbers were recorded in July and August.

In Bengal the death-rate for fevers during 1905 was 24·34 per mille of population against 20·49 per mille in 1904. As in the previous year, the highest number of deaths was recorded in November, and the lowest in July. The highest death-rates during the year were recorded in the districts of Shahabad, Nadia, and Gaya. The Provincial Sanitary Commissioner states that the heavy mortality in Shababad and Gya was due to extensive floods which occurred in August, and lasted about six weeks; the number of deaths recorded under this heading from September to December was as large as that registered during the other eight months of the year. The mortality from fevers was higher than in the previous year both in urban and rural areas, but the increase in rural areas was especially marked.

In Eastern Bengal and Assam the death-rate for fevers during 1905 was 23·68 per mille as compared with 23·60 in the previous year, and an average of 23·35 during the previous decennium. The largest number of deaths was registered in January and the smallest in March. Dinajpur district as usual heads the list with a ratio of 36·15 per mille, Rajshahi coming next with 33·95 and Pabna next with 33·91. Among towns, Barpeta reported a mortality of 33·38 per mille as compared with a quinquennial rate of only 13 per mille; the Provincial Sanitary Commissioner suspects that in this town (see the remarks under small-pox) some cases registered under fevers should really have been classed under small-pox. The recorded number of deaths from *kala azar* was 3,030 as compared with 3,748 in 1904, 5,033 in 1903, and 6,319 in 1902, the districts reporting the largest numbers being Darrang (1,106 deaths), Sylhet (955 deaths), Kamrup (499 deaths) and Nowgong (379 deaths).

In the United Provinces the death-rate for fevers during 1905 was 26·92 per mille, being 3·0 per mille higher than in the previous year, and 2·29 per mille higher than the mean of the antecedent quinquennium. The number of deaths registered under this heading during the year was 1,284,164 against 1,141,029 in 1904. The rate as well as the actual number of deaths in these provinces were considerably higher than in any other province of India. The largest number of deaths was recorded in December and the smallest in August. Saharanpur and Ghazipur were the districts with the heaviest mortality; and, among towns, Brindaban (Muttra) again showed the highest death-rate. In most provinces the rural death-rate was much larger than, often twice as large as, the urban, but in the United Provinces the two rates were practically the same, viz., 26·92 per mille in rural and 26·98 per mille in urban areas.

In the Punjab the total number of deaths recorded during 1905 as due to fevers was 370,047, giving a ratio of 18·04 per mille, which is ·42 per mille lower than the recorded rate in 1904, and 6·65 per mille less than the mean of the preceding quinquennium. December was the month with the largest number of deaths and September the month with the smallest. The Provincial Sanitary Commissioner states that the decrease in the death-rate for fevers was anticipated

as the rainfall during July and August was very scanty. The highest mortality was recorded in the districts of Delhi (24·74), Attock, Mianwali and Muzaffargarh. The Civil Surgeon of Delhi attributed the high mortality in that district to plague deaths in many cases having been classified under fevers. In the other three districts mentioned, deaths from "respiratory diseases and other causes" are supposed to have swelled the number of deaths recorded from fevers. The mortality reported in March was unusually high, especially in some of the plague-infected districts, and the Provincial Sanitary Commissioner thinks it probable that a certain number of deaths really due to plague were registered under fevers. The rural death-rate was only slightly higher than the urban.

In the North-West Frontier Province the death-rate for fevers (20·69) was lower than in the previous year, but higher than the mean of the preceding quinquennium. In the Peshawar District, as usual, the highest rate was recorded. The highest mortality occurred in December; and regarding this the Provincial Sanitary Commissioner states that the heavy mortality in December was probably due to a great variety of diseases, and by no means entirely due to malarial fevers.

In the Central Provinces and Berar the death-rate for fevers rose from 13·54 in 1904 to 17·43 in 1905, every district without exception contributing to this increase. The highest mortality was recorded in September, October, and November and the lowest in January, March, and July. It is thought probable that deaths from plague and influenza were in many cases recorded under fevers.

In the Madras Presidency the death-rate recorded for fevers was 7·2 per mille, which is ·8 per mille less than in 1904, and 1·0 per mille less than the mean of the preceding quinquennium. The death-rate during the year in this Presidency was, as usual, much lower than that recorded in any other of the large provinces. The districts of Vizagapatam and Ganjam, as in the previous year, returned the highest rates, viz., 15·8 and 15·0, respectively. The reported numbers of deaths were larger in November, December, and January, and least in February and March. The Provincial Sanitary Commissioner ascribes the decrease in the recorded fever mortality to people purposely reporting deaths from fevers under other headings in order to escape the enquiries that would be instituted if plague was suspected to be the cause of death.

In the Bombay Presidency the death-rate for fevers was 13·28, which is ·32 per mille less than in the previous year, and 4·12 less than the mean of the antecedent quinquennium. The number of deaths recorded during each of the six months, May to October, did not exceed 20,000, while the number recorded during each of the other months of the year was never below 22,000; the largest number was registered in January. The districts with the highest mortality were Ahmedabad (28·38), Thar and Parkar (22·47) and Broach (20·65); the lowest death-rate was 3·41, recorded in the City of Bombay.

In both Lower and Upper Burma the recorded death-rates under fevers were slightly less than the corresponding figures of the previous year or means of the preceding quinquennium; during 1905, the rate in the former was 8·97 and in the latter 6·76. In Upper Burma the rural death-rate was not much higher than the urban.

Both in Ajmer-Merwara and Coorg the recorded death-rates for fevers were lower in 1905 than in the previous year.

Sale of Quinine.—In Bengal there was a reduction in the number of packets of quinine distributed during 1905, only 35,472 parcels (each containing 102 seven-grain packets) having been sold as compared with 38,041 during 1904. Most of the packets were bought by the villagers during the four months August to November. Sanction has been accorded to the opening of new centres for the distribution of quinine through the agency of village schoolmasters in areas which are distant from dispensaries and post offices.

In Eastern Bengal and Assam the sale of quinine decreased slightly during 1905 as compared with the previous year. In October a scheme was brought into force in Assam by which (1) a depot at the office of the Civil Surgeon has been opened in each district; (2) the number of distributing agents has been increased by including, besides postmasters, the village schoolmaster, the *mauzadar* and the *gaonbura*; and (3) the price of the drug has been reduced so that the retail agents might make a respectable profit.

In the United Provinces the total number of packets of quinine sold during the year was 643,668 against 586,441 in 1904, an increase of 57,227. The post office

was a much more efficient agency than vaccinators and landlords for the sale of the drug. At the end of the year under report, an attempt was made to increase the sale of quinine by means of district boards and aided schoolmasters.

In the Punjab quinine was, as usual, gratuitously distributed in a large number of districts, but, beyond the statement that in the district of Delhi quinine was sold in all the villages, no information regarding the sale of the drug is contained in the Provincial Sanitary Commissioner's Report.

In the Central Provinces and Berar the sale of quinine showed an increase during the year, 4,887 packets having been sold as compared with 4,781 in 1904. As usual, postmasters sold the greatest number of packets; village schoolmasters sold 125 packets, patwaris 53, and stamp vendors 37.

In Burma the sale of quinine has met with a fair amount of success, more than twice as many packets having been sold by vaccinators as by postmasters. The Burman apparently believes in the efficacy of quinine, but objects to its taste; consequently, many officers have urged that quinine should be available in the form of tabloids.

Details are wanting regarding quinine sales in the North-West Frontier Province, Madras, and Bombay.

Dysentery and Diarrhœa.—The number of deaths recorded in British territory under the heading of dysentery and diarrhœa rose from 240,655 in 1904 to 264,124 in 1905, and the death-rate per mille of population from 1·06 to 1·17. As shown in the statement of the first paragraph of this section, the death-rate recorded under this heading during 1905 is, except for 1·21 recorded in 1903, the highest in the quinquennial period 1901-5. A higher mortality than in 1904 was reported in all the provinces except the North-West Frontier Province and the Bombay Presidency; but the increased mortality during the year under review was due chiefly to a severer prevalence of the diseases in the Central Provinces, Eastern Bengal and Assam, and the Madras Presidency. In India as a whole the largest numbers of deaths from these diseases were recorded in August and September, and the smallest in February and March; but there are frequently wide differences in the seasonal incidence in even adjacent provinces.

In Bengal the death-rate from dysentery and diarrhœa in 1905 was ·90 per mille of the population as compared with ·82 in 1904 and ·99, the average of the quinquennial period ending 1904. The districts in which the highest death-rates were recorded were, as usual, Howrah, Patna, Puri, Calcutta, Cuttack, Darjeeling and Hooghly. The urban morality was more than four times as large as the rural. The Provincial Sanitary Commissioner reports, as the results of a special enquiry, that in Orissa infantile diarrhœa is extraordinarily common, and is the chief cause of the high death-rate, the number of deaths of children under five years being nearly equal to that of persons above that age; that many more deaths are due to acute diarrhœa than to dysentery; and that the bad water-supply and the ignorance of the people are the cause of the prevalence of these diseases; that in Howrah and Hooghly the type of diarrhœa that prevails is the terminal diarrhœa of chronic malaria and *kala-azar*, infantile diarrhœa being comparatively uncommon; that in Patna, where the *chaukidars*—the reporting agents—are less intelligent than in other parts of Bengal, 61 per cent. of the deaths reported as due to dysentery and diarrhœa were found, after investigation, to be from other causes, cholera being the most important source of error. In Eastern Bengal and Assam the mortality from dysentery and diarrhœa during 1905 was considerably higher than that of the previous year, and also higher than the average of the preceding quinquennium or decennium. The heaviest mortality prevailed in the tea districts of the Assam and Surma Valleys; Lakhimpur reported a district ratio of 6·8 per mille, Sibsagar 4·6, Darrang 3·1, Cachar 3·6 and Sylhet 2·0. The only district in Eastern Bengal which reported a comparatively high rate was Dacca with 1·45 per mille. In the United Provinces the recorded mortality from dysentery and diarrhœa was higher than in the previous year, but lower than the average of the preceding quinquennium. The greatest number of deaths from this cause took place in June and the smallest in March. As in previous years the mortality was greatest in the districts of Garhwal (11·39 per mille), Almora (4·20) and Ballia (3·07); the rates in these three districts in 1904 were 8·01, 3·59, and 2·81 per mille, respectively. The urban death-rate was more than five times as high as the rural. The recorded mortality from dysentery and diarrhœa in the

Punjab during 1905 was also greater than that of the previous year, but considerably less than the average of the quinquennium 1900-04. The highest rates were recorded in the districts of Simla (2·25, Rawalpindi (1·76), Jhang (1·68), Ambala (1·34), and Kangra (1·02). Both in 1904 and in 1905 the death-rate in towns was about four times that in villages. In the North-West Frontier Province 562 deaths against 610 in the previous year were attributed to dysentery and diarrhœa; the death-rate (·28) during the year was the same as the mean of the preceding five years. Dera Ismail Khan was the district most affected. There was a large increase in the mortality from dysentery and diarrhœa in the Central Provinces and Berar during 1905, the number of deaths from these diseases being 35,879 against 26,742 in 1904; the Berar districts alone accounted for 21,276 out of the total of 35,879 deaths. The death-rate for these diseases in the Central Provinces and Berar combined was 3·02 per mille—the highest among all the provinces during the year. The incidence was especially heavy during August, September and October and, in the opinion of the Provincial Sanitary Commissioner, was probably due to a late but heavy rainfall. The highest death-rates in the districts were 10·20 per mille in Akola, 8·76 in Buldana, and 7·37 in Amraoti—all in Berar; the highest district rates in the Central Provinces were 4·91 in Wardha and 3·23 in Jubbulpore. There were only two districts (Balaghat and Bhandara) which furnished lower rates than in the previous year. No cholera was reported during the year from the Berar districts, but the Provincial Sanitary Commissioner does not think that any deaths really due to cholera were recorded under dysentery and diarrhœa. The death-rate in municipalities was 3·77 per mille as compared with 2·93 in rural areas. In Madras the death-rate from dysentery and diarrhœa was 1·4 per mille in 1905 against 1·3 in 1904 and an average of 1·2 in the quinquennium 1900-4. The highest district-rates were 11·2 in Madras and 4·4 in the Nilgiris. The Provincial Sanitary Commissioner states that the prevalence of these diseases in Madras was due to "the influx of pauper ryots and coolies into the city from the adjoining districts in quest of labour," to the consumption of inferior grains and other articles of food by the poorer classes, and to the insufficient and polluted water-supply. Compared with the rural death-rate (1·1), the urban (4·0), was slightly higher than usual during the year. In Bombay the death-rate per mille and the total number of deaths from dysentery and diarrhœa showed a considerable reduction during 1905 in comparison with the figures of the previous year, and the averages of the previous quinquennium. The death-rate was 3·00 per mille as compared with 3·33 in 1904 and a mean of 4·87 during the quinquennium 1900-4. It is worthy of note that in 1905, the death-rate from dysentery and diarrhœa in Bombay was not the highest provincial rate, but followed that recorded in the Central Provinces and Berar. These diseases were most prevalent during August and September, most deaths as usual having been registered in August; they were least prevalent in November and December. The highest ratios were recorded in the districts of Khandesh (9·53), Poona (6·03), Ahmednagar (5·73), Sholapur (5·03) and Nasik (4·80). The death-rate in rural areas was 2·91 per mille, while that in towns was 3·61; the relatively high rural death-rates in this Presidency and in the Central Provinces and Berar are noteworthy. In Lower Burma the recorded death-rate from dysentery and diarrhœa in 1905 was 1·43 per mille as compared with 1·27 in 1904 and a mean of 1·48 in the preceding quinquennium; in Upper Burma it was ·44 per mille as compared with ·31 in 1904 and a mean of ·33 in the preceding quinquennium. In Lower Burma the urban rate was more than three times as high as the rural, but in Upper Burma the urban was ·60 per mille while the rural was ·43. The relatively high death-rate in the towns of Lower Burma is attributed to the general use in these towns of cess-pits for the disposal of night-soil and to temporary floodings of these towns, *e.g.*, Thayetmyo, during the year under review. In Ajmer-Merwara, 424 deaths from dysentery and diarrhœa were registered in 1905; in Coorg 96 deaths.

General History of Vaccination.

(For Statistical Tables, *see* page 149).

Vaccination in India.—During the year 1905-06, the number of persons vaccinated by all agencies in British India reached a total of 9,277,896, which indicates a steady continuance of the increase observed in the work of the vaccination department during the past three years—1902-03 (8,431,564 operations), 1903-04 (8,457,298) and 1904-05 (8,944,749). With the exception of the Madras and Bombay presidencies every province shared in the increase, the rise in the figure in Bengal (222,999) being specially notable; Eastern Bengal and Assam and Burma followed with increases of 76,947 and 75,924 operations, respectively. The decreases in the Madras Presidency (18,279) and in the Bombay Presidency (12,669) were comparatively insignificant and will be explained in the paragraphs relating to these provinces; in the former, however, the number of successful cases in 1905-06 (1,296,312) was greater than in the preceding year (1,242,717). Taking British India as a whole, the primary cases numbered 8,586,770 as compared with 8,351,257 in 1904-05, and the percentage of success in the two years was 97·20 and 96·04, respectively. Revaccinations increased from 593,492 in 1904-05 to 691,126 in 1905-06, but the percentages of success fell slightly from 74·71 to 74·20. In the provinces the percentage of success varied in primary cases between 99·19 in the Punjab and 90·80 in Burma, and in revaccinations between 84·78 in the United Provinces and 53·33 in Burma. The mean number of vaccinations performed by each vaccinator was 1,480 as compared with 1,487 in the previous year, the figures in the provinces ranging from 3,162 in the North-West-Frontier Province and 996 in Ajmer-Merwara. Vaccination at dispensaries continued to show an increase, there having been 207,421 operations compared with 203,705 in 1904-05, Bengal (122,105) contributing by far the largest number to the total, followed by the Central Provinces and Berar (28,790), Eastern Bengal and Assam (27,735) and Burma (17,507). The comparatively insignificant number of operations at dispensaries in the United Provinces (655) is explained by the fact that no special vaccinators are attached to those institutions, operations being performed by medical subordinates.

The mean proportion of the population successfully vaccinated, which had been 33·32 per mille in 1903-04, and 34·79 per mille in 1904-05, rose to 36·39 per mille in 1905-06. As in the preceding year the ratio was highest in Coorg (55·45) and lowest in Bombay (27·35).

On an estimated birth-rate of 40 per thousand of the census population, 43·83 per cent. of the infants were protected compared with 42·46 per cent. during the preceding year. The percentage in the several provinces varied greatly, from 76·75 in the Central Provinces and Berar and 62·54 in the Punjab to 21·27 in Burma and 11·68 in Coorg.

The total cost of the department which had been £80,245 in 1904-05, increased to £85,509 in 1905-06, and the mean cost of each successful case rose to $2\frac{5}{12}$d. The cost of each case in the provinces ranged between $8\frac{1}{4}$d. in Bombay and about $\frac{11}{12}$d. in Eastern Bengal and Assam.

Vaccine lymph.—In the paragraphs relating to individual provinces, reference is made to the vaccine material used in each, and here it is necessary to notice only the more important facts connected with the supply of vaccine.

The Shillong vaccine depôt for the supply of material to Eastern Bengal and Assam is now independent of vaccine from outside sources and can maintain its own supplies with certainty. The Patwa Dangar lymph depôt at Naini Tal is now well equipped and its utility to the United Provinces has largely increased, while the work of the depôt at Belgaum for the Bombay Presidency has been successfully launched. The proposal to establish lymph depôts in the North-West Frontier Province has been abandoned in view of the satisfactory and economical arrangements in force for obtaining vaccine from the Punjab depôt. Useful experimental work in the preparation of vaccine was done by Major Entrican, I.M.S., at the Meiktila depôt which supplies all the lymph for Burma, except Rangoon where there is a local depôt. Major Entrican devised two machines for filling lanoline vaccine in tubes and glycerinized and quinated lymph in capillary tubes, respectively. The apparatus does efficiently, in a few minutes, work which formerly occupied several hours.

Bengal.—The figures of the vaccination operations in Bengal during the year 1905-06 exclude those relating to the districts transferred to the new province of Eastern Bengal and Assam, and to admit of comparison, the figures of the year 1904-05 used below also exclude those relating to the transferred districts. The Sambalpur district was added to Bengal during the year under report, but as the vaccination figures of the district are not available they have not been included in the provincial figures.

The total number of operations performed in the remodelled province during the year 1905-06 was 2,041,230 against 1,818,231 during 1904-05. Of these totals, 1,904,625 and 1,759,124 were primary cases, and 136,605 and 59,107 revaccinations, respectively, in each of those years: the net increase was, therefore, 145,501 primary cases and 77,498 revaccinations, which is very satisfactory. The recovery in the number of revaccinations is largely due to the special efforts made by the Corporation of Calcutta to combat the severe outbreak of small-pox during the year, there having been an increase of over 50,000 revaccinations in Calcutta. Of the 33 districts of the province, 23 show an increase and only 10 a decrease. The most noticeable increases occurred in the districts of Saran (24,254), Midnapore (17,016), Jessore (12,643), the Tributary States of Orissa (12,142), Shahabad (11,631), and Nadia (11,273), while the decrease was most marked in the districts of Balasore (13,273), Sonthal Parganas (12,465), Birbhum (6,310) and Purnea (5,782). The increased work is attributed to various causes, among them more careful supervision; more energetic working; less prevalence of plague; the greater prevalence of small-pox, and in some places the introduction of the system of rewards to vaccinators. The decrease in Balasore is said to be due to the inefficiency of the staff, some of whom have been dismissed, and in the Sonthal Parganas and Purnea to the prevalence of sickness.

Generally, it is hoped that much improvement will be effected in the department in consequence of the introduction of the scheme recently sanctioned for the education of vaccinators, and the general substitution of prepared lymph for arm-to-arm vaccination.

The ratio of success in primary operations rose from 98·80 per cent. in 1904-05 to 99·13 per cent. in 1905-06, and in revaccinations from 61·63 to 66·29 per cent.

Vaccination was carried on with calf lymph (151,080 primary operations) lanoline lymph (400,847) and from arm-to-arm (1,352,698), the figures showing an increased use of calf and preserved lymph, and a smaller number of arm-to-arm cases. The percentages of success by each method was calf lymph 98·92 as compared with 99·30 in the previous year, lanoline lymph 96·57 as compared with 95·81, and arm-to-arm 99·21 as compared with 98·95. The ratios of success in revaccination by each method in 1905-06 were 58·81, 53·98 and 78·02 per cent., respectively.

At an estimated birth-rate of 40 per mille of the population, 39·18 per cent. of the infant population were successfully vaccinated, compared with 34·41 per cent. in 1904-05 and 29·36 per cent. in 1903-04, which shows that infant vaccination is making progress. In municipalities the rate of protection of infants rose to 85·82 per cent., from 65·08 per cent. in the year preceding. There was a satisfactory improvement in Calcutta where nearly half the available infant population were protected, compared with about one-fourth only of the number available in the previous year.

As in the report for 1904-05, there is again no information as to the quantity and quality of the lymph issued from the Darjeeling and Calcutta depôts during the year under report, nor is there any reference to the working of the system introduced last year of issuing lymph direct to the operators instead of through superior officers. The Darjeeling depôt as usual supplied lymph to the Nepal Darbar and the Sikkim State—380 and 860 grains respectively—the results from which were reported to have been satisfactory.

The cost of the department was £10,520 against £9,056 in 1904-05—excluding the figures for Calcutta in both years which were not received—and the cost of each successful case, $1\frac{1}{4}$d. as compared with $1\frac{1}{12}$d. in each of the two preceding years.

Eastern Bengal and Assam.—The work of the vaccination department in the new province, an account of which appears for the first time in this report, for the year 1905-06 is compared with that done in 1904-05 in Assam and the Bengal districts transferred to the new province. The total number of vaccination operations, which aggregated 1,352,079 in 1904-05, rose to 1,429,026 in 1905-06. The

distribution of the total was 1,313,998 primary cases in 1904-05 and 1,385,538 in 1905-06, showing an increase of 71,540 cases, and in revaccinations 38,081 in 1904-05 and 43,488 in 1905-06, or an increase of 5,407. The percentages of success also improved from 97·09 to 98·28 in primary cases, and from 56·95 to 71·71 in re-vaccinations. The most marked increase in the number of operations occurred in the Chittagong district (53,000), and the Faridpur (18,000) and Noakhali (11,000) districts also showed large increases. In Chittagong the increase was due to special efforts made by the vaccinating staff owing to an outbreak of small-pox, the result being the highest figures on record for the district. In Faridpur opposition was overcome with very satisfactory results by calling on village headmen to show cause why vaccination should not be made compulsory. On the other hand in the Dacca district there was a fall of 21,000 operations as compared with the preceding year, which has been explained by the special activity in vaccination work in 1904-05 owing to an outbreak of small-pox, and the fact that the number of operations in that year exceeded the average. For the decreased work in other districts various reasons have been adduced. On tea gardens 15,143 primary operations were performed, of which 94 per cent. were successful.

On an estimated birth-rate of 40 per thousand of population 33·62 per cent. of the infant population were protected against 29·67 per cent. in 1904-05. Of the available number of children in towns 70·9 per cent. were successfully vaccinated.

Vaccination was carried out during the year with humanized vaccine, with manufactured vaccine (glycerine or lanoline) and with calf vaccine. The use of human lymph is to be discontinued as larger supplies of manufactured vaccine become available, and in any case it is not to be used in areas where vaccination is compulsory. The Shillong vaccine depôt is now independent of vaccine from outside sources and can maintain its own supplies, the quality of which is uniform and good, with certainty.

The department cost £5,120 in 1904-05 and this increased to £5,340 in 1905-06. In both years, however, each successful case cost $\frac{1}{1\frac{1}{2}}$d.

United Provinces.—The total number of vaccination operations in the United Provinces in 1905-06 was 1,695,416, an increase of 23,656 operations compared with the results of the preceding year. The number of successful primary operations was 1,544,152 in 1905-06 against 1,517,491 in 1904-05, or an increase of 26,661, but the number of successful revaccinations fell from 77,209 in the preceding year to 76,260 in the year under report. The percentage of success in primary cases was 97·93 in 1905-06, or a little higher than the rate of 97·62 in 1904-05; re-vaccinations were, however, less successful, 84·78 per cent. compared with 86·51 per cent. In 34, as compared with 31 in the previous year, of the 49 districts in the province, there was an increase in the number of successful primary operations. The districts showing the largest increases were Allahabad (4,126), Aligarh (4,049), Gonda (3,905) and Agra (3,427). Among the districts showing a falling off in the number of successful primary operations are Ballia (5,827), Sultanpur (5,607), Banda (3,848), Rae Bareli (2,223) and Benares (2,180). For the decrease in Ballia the provincial Sanitary Commissioner accepts the explanation that, apart from the effects of plague and cholera, the amount of work done in previous years has reduced the number of the susceptible population; elsewhere, the prevalence of cholera, the deputation of experienced vaccinators to the *kumbh mela* at Allahabad, and, in places, slack work on the part of vaccinators, account for the fall.

On an estimated birth-rate of 40 per mille, the number of infants successfully vaccinated represent 49·57 per cent. of those available, which is less than the percentage of 52·11 protected in 1904-05. In municipalities, infants were protected at the rate of 102·13 per cent., on the figures of birth *minus* deaths neglecting any outside addition to the number thus available, showing a recovery from the rate of 89·6 in 1904-05 to which it had fallen from 98·2 in 1903-04.

Bovine lymph depôts were maintained at Lucknow and Patwa Dangar (Naini Tal). The latter is now well equipped and its utility to the province has largely increased. Considerable difficulty was experienced in getting a good and regular supply of calves at a reasonable price. Of the 96 calves vaccinated, 88—78 cow and 10 buffalo—were vaccinated successfully. The average quantity of crude lymph yielded by a cow calf was 196 grains, and that by a buffalo calf 249 grains. Lanoline lymph was prepared only when requisitioned, glycerine lymph having been substituted for stock purposes and found to give better results. During the year

74,800 tubes and 24½ drams in bulk of glycerine lymph and 30 drams of lanoline lymph were issued. Lymph was regularly supplied from the depôt to all districts in the plains. The working of the institution is regarded as very satisfactory.

The cost of the department amounted to £10,216 or somewhat more than the cost of £9,909 in the preceding year, but the cost of each successful case 1½d. was the same in both years.

Punjab.—The working of the vaccination department in the province continued to show satisfactory improvement during the year 1905-06. The total number of operations performed by all agencies amounted to 748,739, showing an increase of 28,968 cases, equivalent to an increase of four per cent. on the figures of 1904-05, and of about six per cent. on the average of the previous quinquennium. This result is no doubt due to the close supervision exercised by the Sanitary Commissioner during the vaccine season over the work of the vaccinators and the inspections performed by the Superintendents. In primary work there was an increase of 56,291 cases compared with the number in the preceding year, but revaccinations showed a fall of 27,323, leaving a net increase of 28,968 operations during the year under report. The fall in the number of revaccinations, however, is explained by the system under which one-eighth part of a district is to be revaccinated every year, which was introduced during the preceding working season only, and time must elapse before its effects are apparent. At the same time it is necessary to allow for the fact that the people are prejudiced against revaccination, which in certain districts is much less popular than the primary operation. The revaccination of girls is unpopular in all districts. The percentage of success in primary cases was 99·19 in 1905-06, and 99·17 in 1904-05; in re-vaccinations the percentage rose to 83·38, from 81·04 in the preceding year.

On an estimated birth-rate of 40 per mille, 62·54 per cent. of the infants were protected, while in 1904-05 and 1903-04 the rates were 56·25 and 58·23 per cent., respectively. In municipalities 85 per cent. of the available children in the towns where the Vaccination Act is in force and 66 per cent. in those where vaccination is not compulsory, were successfully vaccinated; the corresponding percentages in 1904-05 were 73 and 60, respectively.

The chloroformed glycerine lymph manufactured at the Central Vaccine Institute, Lahore, proved most satisfactory. Of the 100,768 primary vaccinations performed with it during the year, there was a case success of 99·94 per cent. and an insertion success of 99 per cent., the corresponding figures in 1904-05 having been 33,210 primary cases, and case and insertion successes of 98·72 and 94·90 per cent., respectively.

The cost of the department was £6,513 or £125 more than in 1904-05, excluding the accounts of 1904-05 relating to the Kangra district which were lost in the earthquake of April, 1905. The increase is chiefly due to the employment of additional establishment for the Lyallpur district. The cost of each successful case was 2¼d. or 1½d. less than in 1904-05.

The vaccination work in the larger Native States also improved generally. In the Patiala State the number of primary operations rose from 48,490 in the preceding year to 54,086 in 1905-06, and the number of revaccinations from 30,992 to 31,034. In the other large States the work done was, Bahawalpur 18,804 primary cases compared with 20,065, nearly all primary cases, in 1904-05. In Kapurthala the recorded results were (the figures in brackets are those for the preceding year) 5,578 (4,827) cases, Nabha 1,074, Jind 6,978 (6,697) and Faridkot 5,185 (5,488), all primary operations. The revaccination work was, however, most insufficient, the total number of cases amounting to 386 only. The percentage of success in primary cases ranged between 98·09 in Faridkot and 89·77 in Nabha.

North-West Frontier Province.—The vaccination operations in the Frontier Province during the year 1905-06 numbered 100,866 compared with 77,042 in 1904-05, or an increase of 23,824. The primary cases numbered 87,771, against 74,267 in the previous year, and revaccinations 13,095 against 2,775. The percentage of success in the former was 98·56 and in the latter 84·45, compared with 98·96 and 75·39, respectively, in 1904-05. There was a marked increase in the number of operations in all districts, the political agencies and cantonments, and also in the work done by the dispensary staff, the last-mentioned performing no less than 2,845 operations against 104 only last year. The greatest rise occurred in

the Hazara district, the numbers being 16,835 cases in 1904-05 and 26,417 in 1905-06, but of the total increase, over 7,000 were revaccinations. The result in Hazara is no doubt in a measure due to the number of vaccinators having been increased in April 1905 from three to six. Large increases also occurred in the Dera Ismail Khan and Kohat districts. Vaccination work is conducted in the Kurram and Tochi agencies and the sub-agency of Chitral, the best work being done in the first-mentioned. Efforts are to be made to introduce vaccination into other political agencies, but the local administration doubts if they will be attended with much success. The special vaccinator entertained for the Sherani Country succeeded in vaccinating 3,843 persons, and in the Amb territory 1,249 operations were performed by a vaccinator of the Hazara district. Both Sherani and Amb are foreign territory.

On an estimated birth-rate of 40 per mille, 58·92 per cent. of the infants were protected against 52·48 per cent. in the preceding year. The Vaccination Act is now in force in all save two of the municipal towns of the province, and the question of extending the Act to these two is again to be urged. The number of infants successfully vaccinated in those two towns was, however, fairly satisfactory. In all the towns a mean of 72·3 per cent. of the available number of infants were successfully vaccinated.

The vast majority of vaccination operations were performed with animal lymph, human lymph hardly being used except in the Sherani Country and the Kurram Valley. In Peshawar vaseline lymph and glycerine lymph were largely used owing to the difficulty of obtaining buffalo calves in the district. The requirements of lymph for the province are met by obtaining preserved lymph from the Punjab Vaccine depôt at the beginning of the season and vaccinating buffalo calves; this secures a good supply during the rest of the year. The idea of establishing lymph depôts in the province has been abandoned in view of the economical and satisfactory arrangement for obtaining requirements from the Punjab Vaccine depôt.

The cost of the department was, £776, as compared with £748 in the preceding year, but the cost of each successful case fell from $2\frac{5}{12}$d. to 2d.

Central Provinces and Berar.—The total figures relating to vaccination in the Central Provinces and Berar include the work done in the Feudatory States and at dispensaries. The figures for 1905-06 exclude those of the Sambalpur district which has been transferred to Bengal, and also of the Native States transferred to that province for which figures were not forthcoming. The figures for 1904-05, where used for comparison, also exclude the Sambalpur district.

The total number of operations conducted in the province during 1905-06, numbered 626,138 against 597,177 in 1904-05, of which 551,140 were primary cases and 74,998 revaccinations, the corresponding figures for the preceding year being 540,187 and 56,990, respectively. The percentage of success was 98·59 in primary cases and 72·30 in revaccinations. Excluding Feudatory States, 559,443 persons were vaccinated against 539,516 in 1904-05, and of the former 491,818 were primary cases and 67,625 re-vaccinations; the percentages of success were 97·26 and 62·83, respectively. The increase in primary work of about 6,000 cases is attributed to the high birth-rate of the year, and in revaccinations of about 14,000 cases, to the efforts made to induce people to get themselves revaccinated, aided in some districts by the prevalence of small-pox. In the Feudatory States 59,322 primary vaccinations were performed compared with 54,334 in 1904-05, and 7,373 revaccinations compared with 3,327. The percentage of success claimed was 96·81 against 97·09 in primary cases and 84·03 against 85·75 in revaccinations.

On the whole 44·81 per mille of the population were successfully vaccinated in 1905-06, as compared with 42·83 per mille in 1904-05 which, bearing in mind the prevalence of plague in many parts of the province during the year, is considered to be satisfactory.

Estimating the birth-rate at 40 per mille of the population, 76·75 per cent. of the infants were successfully vaccinated and in municipalities 96·93 per cent. of the number available.

The various kinds of lymph used during the year were fresh calf lymph 32,536 cases (93·48 per cent. successful), glycerine calf lymph 502,401 cases (93·14 per cent. successful), human lymph 19,555 cases (97·60 per cent. successful) and lanoline

lymph 4,951 cases (68·79 per cent. successful). The use of glycerine calf lymph has steadily increased, but it is not explained why the percentage of success with it, which was 96·14 in 1904-05, fell to 93·14 in the year under report.

The cost of the department was £4,425 or £267 more than in 1904-05 the increase being due to various causes. Each successful case cost $1\frac{1}{2}$d. in both years. In the Feudatory States, the department cost £317 or £20 more than in 1904-05, but the cost of each successful case fell to $1\frac{1}{4}$d. from $1\frac{1}{3}$d.

Madras.—The total number of vaccination operations performed by all agencies in the Presidency numbered 1,464,990 during 1905-06. Primary cases showed a decrease of 49,244 and revaccinations an increase of 30,965 during the year, leaving a net decrease of 18,279 operations compared with the work done in 1904-05. It is satisfactory, however, to record that the total number of successful vaccinations, which had been 1,242,717 in 1904-5, rose to 1,296,312 in 1905-06, while the percentages of success in primary cases and in re-vaccinations rose from 87·38 and 74·51 to 92·67 and 76·02, respectively. The explanation of the decreased outturn of work in some districts is the short supply of vaccine paste from the King Institute and the absence of vaccinators without substitutes being appointed. In regard to the shortage of the paste supply during certain months of the year, it has been ascertained that it was due to the unfavourable state of the season in the Chingleput district and to the poor condition of the calves.

On the estimated birth-rate of 40 per mille, 30·09 per cent. of the infants were successfully vaccinated, which shows an improvement on the rates of 28·29 and 27·57 recorded in 1904-05 and 1903-04, respectively; in municipalities 67·9 per cent. of the available infants were protected against 66·5 per cent. in the preceding year.

Lanoline lymph, manufactured at the King Institute, Madras, was used exclusively in local fund areas with a percentage success of 92·3, against 86·6 in the previous year, and almost exclusively in the municipalities with a percentage success of 95·6. Nearly 600 operations were performed in municipalities with lanoline lymph supplied by the Bangalore Institute, the percentage of success being 96·7. Locally prepared glycerine lymph was also used in municipalities and was successful at the rate of 99·4 per cent. The results during 1905-06, from the lanoline paste prepared at the King Institute show a marked improvement on those during 1904-05, which is accounted for by the vaccinators having become more familiar with the use of the lymph. A Deputy Inspector of Vaccination was deputed to give instruction in the use of this description of lymph in the more backward districts.

The cost of the department which had been £18,491 in 1904-05, rose to £19,628 during 1905-06, and the cost of each successful case rose by $\frac{1}{12}$d. to $3\frac{2}{3}$d.

Coorg.—In Coorg the increase in the number of vaccinations during 1904-05 was more than maintained during 1905-06, a total of 11,291 operations having been performed of which 9,306 were primary operations and 1,985 revaccinations, showing increases of 405 and 508, respectively, on the figures of the preceding year. The percentage of success in primary cases was 93·21 compared with 95·99 in 1904-05, and in revaccinations 76·26 compared with 86·43. Calf lymph was used, but no reason is given for the decline in the ratios of success.

The cost of the department was £183, or a little below the sum of £185 spent in 1904-05, and each successful case cost $4\frac{1}{2}$d. or $\frac{1}{6}$d. less than in the previous year.

Bombay.—The steady increase of vaccination work which has taken place in the Presidency during recent years, was not continued during 1905-06, when the total number of operations was 656,338 compared with 669,007 in 1904-05. The decrease occurred in the Western, Central and Presidency Circle registration districts, the explanation offered being the large number of persons vaccinated in the previous year owing to the prevalence of small-pox, and an adverse season in the Central registration district scattering the people. Of the 656,338 operations performed, 610,985 were primary cases and 45,353 revaccinations, the corresponding figures for 1904-05 being 607,064 and 61,943, respectively, so that the net decrease of the year was brought about by the smaller number of revaccinations. The percentages of success in 1905-06 were somewhat lower than in the previous year—primary cases 97·56 against 98·52, and revaccinations 76·13 against 79·12.

On the estimated birth-rate of 40 per thousand of population, 52·32 per cent. of the infants were protected against 52·99 per cent. in the previous year, but according to the provincial Sanitary Commissioner's calculation of births *minus* deaths of infants under one year of age, 81·08 per cent. of the infants available were protected.

Vaccination was conducted from calf to arm, with glycerinated calf lymph and with lanolinated vaccine: in Sind, except for a few operations, the arm-to-arm process was employed. In the Southern registration district, vaccination with preserved lymph manufactured at the Vaccine Depôt, Belgaum, was carried on successfully, and in the words of the Deputy Sanitary Commissioner "the increase in the work cannot be attributed to a fall in the epidemicity of plague but rather to vaccination with preserved vaccine lessening the difficulties confronting the vaccinator, and also possibly to the new method being more popular with the people." After trials at the Vaccine Depôt at Belgaum with various kinds of lymph, it has been decided to adopt chloroformed glycerine lymph which was largely used in the Southern registration district and is being gradually introduced into the other districts.

The cost of the department rose from £19,028 in 1904-05 to £20,087 in 1905-06; the cost of each successful case in those years being $7\frac{3}{4}$d. and $8\frac{1}{4}$d., respectively.

Burma.—In Burma the total number of vaccination operations was 488,927 or 75,924 more than in 1904-05. Of the total operations, 426,935 were primary cases and 61,992 revaccinations, compared with 380,686 and 32,317, respectively, in the previous year, so that there was an increase in both classes of work, the number of revaccinations being almost doubled. The percentage of success was also higher, in primary cases 90·80 in 1905-06 compared with 84·67 in 1904-05, and in revaccinations 53·33 compared with 47·99. The Rangoon municipality contributed 24,081 cases to the increase in the total of the previous year "largely due to belated vigour in vaccinating, following the severe epidemic of small-pox which prevailed during the year."

The vaccine used was bovine lymph obtained from the Meiktila Vaccine depôt, except in Rangoon where lymph, the quality of which is condemned by the provincial Sanitary Commissioner, is prepared at a local depôt. The lymph supplied by the Meiktila depôt was satisfactory; it was of three descriptions, viz., lanoline vaccine, glycerinated-vaccine and quinated-vaccine. Major Entrican, I.M.S., who is in charge of the depôt, found that in point of duration of vitality lanoline is preferable as a medium, but that in the unskilled vaccinators' hands the more fluid glycerine forms are more readily manageable. Arrangements are to be made for the new vaccination staff to be entertained to be given a course of training at the Meiktila Vaccine Depôt in theoretical and practical vaccination and allied subjects and better results may, therefore, be anticipated.

The cost of the department rose from £6,677 in 1904-05 to £7,631, but the cost of each successful case fell to $4\frac{3}{4}$d. from $5\frac{1}{6}$d. in the year before.

Ajmer-Merwara.—In this small province the total vaccination operations showed a trifling increase from 14,713 operations in 1904-05 to 14,935 in 1905-06. The primary cases numbered 14,510 or 300 more than in the previous year, and revaccinations 425 or 78 less. The percentage of success in primary cases was 95·50 against 99·08 per cent. in 1904-05 and in revaccinations 81·65 against 86·28 per cent.

The department cost £190 and each successful case $3\frac{1}{12}$d. in 1905-06, as compared with £177 and $2\frac{11}{12}$d. respectively, in 1904-05.

Sanitary Works.

Bengal.—In the province of Bengal before the partition there were, excluding Calcutta, 161 municipalities and their income in 1904-05, excluding an opening balance of £62,956 was £385,153 or £18,608 more than in the previous year. Of the total income 36·40 per cent. was spent on sanitary works, 12·48 per cent. on roads, 5·66 per cent. on public safety and 31·63 on other requirements. The actual expenditure on sanitation included £20,967 on water supply, £13,439 on drainage, and £90,719 on conservancy.

The expenditure on water-supply was £8,099 less than in 1903-04 as a result of the large capital expenditure in that year; on conservancy and drainage expenditure increased by sums of £3,977 and £2,306, respectively.

There is evidence of considerable activity in municipal sanitation in Bengal; water supplies are being improved, drainage schemes undertaken and conservancy improved. Attention has been focussed upon the biological method of disposing of sewage on account of the objections raised to the discharge into the river of effluents from the installations attached to the mills on the banks of the Hooghly, and Dr. Gilbert Fowler of Manchester was engaged by the Government of Bengal to enquire into the matter. He arrived at the end of the year and his report is awaited. In the meantime Captain Clemesha, I.M.S., the Sanitary Commissioner, succeeded in devising a method for the practical sterilisation of effluents by the use of chloride of lime.

The work of the different district boards has mainly had to do with measures for the prevention of plague and cholera, sanitary arrangements at fairs, clearance of jungle in the neighbourhood of villages and the improvement of local drainage.

There were two meetings of the Sanitary Board during the year; but, as usual, most of the work was carried on by the circulation of files among the members. The more important matters considered at the meetings were the appointment of an Assistant Sanitary Engineer, the Monghyr waterworks project, the Howrah drainage project, and the modification of the rules for the preparation of drainage and water-supply schemes.

Preliminary estimates were prepared for the Monghyr waterworks to cost £20,867, of which it is proposed to raise £15,258 by local subscriptions; and for the Rampur-Boalia waterworks, the water to be pumped from a large well for which a suitable site has been found.

Detailed estimates were prepared for the Barisal waterworks and the Khulna filtered water-supply scheme. Among the schemes considered during the year were the Howrah drainage project, the Garulia drainage project, the Baranagore drainage scheme, the Titaghar drainage scheme, the Budge-Budge drainage scheme, the Cossipur-Chitpur drainage scheme, drainage schemes for Puri, Berhampore, Uttarpara, Deoghar, Khulna, and Azimgunge, and schemes for the improvement of the water-supply of Kurseong and the supply of unfiltered water to Cossipur-Chitpur.

The scheme for the supply of filtered water to Faridpur proved so successful that, at the instance of the Commissioner of the Dacca division, the Board, with the sanction of Government, distributed the design and estimate of cost of the filter beds to all the small municipalities. The scheme is very simple; it consists of a tank with two filter beds on the bank, a clear water reservoir fitted with taps and arrangements for pumping.

Eastern Bengal and Assam.—The new province was constituted after the end of the financial year to which this section relates, and the facts regarding the income and expenditure of most of the municipalities are included in the details given under Bengal. In Eastern Bengal and Assam there are 44 municipalities, two stations, Shillong and Sibsagar, and three unions, Jorhat, Golaghat, and Habiganj. The total income excluding opening balance was £86,328, of which 41·71 per cent. was spent on sanitary works of one kind or another.

A Sanitary Board was formed, consisting of the Senior Member of the Board of Revenue, the Chief Engineer and Sanitary Commissioner, but no meeting was held.

United Provinces.—Municipal sanitation continues to make rapid progress in these provinces. The water-supply works at Agra, Allahabad, Benares, Cawnpore, Lucknow, and Meerut gave excellent results throughout the year, and extensions were made and improvements introduced in most cases. At Meerut where the water is taken from an irrigation canal, the water was of most excellent quality, the result of the examination of 268 samples showing an average of 2·76 microbes per c.c. One of the filters in which the rate of filtration is controlled by a special metre devised by the Sanitary Engineer, Mr. Aikman, gave even better results, the average number of microbes per c.c. being only 1·46. At Naini Tal, where the pumps had to be worked throughout the year on account of scanty rainfall, there was a considerable increase in expenditure owing to more coal being required and to some new machinery being necessary. At Mussoorie the scheme for extending the water-supply and introducing electric lighting is in progress.

Good progress was made with the drainage and sewage works at Benares, Cawnpore, and Agra. At Agra the sullage is run on to a sandy island in the bed of the river and is used to irrigate crops of tobacco which promise to repay the cost of the sullage farm. At Lucknow the drainage works have been pushed on rapidly; 829 acres have been completely paved and 29,941 feet of underground storm-water sewers have been built. During the year nearly 44 miles of drains were completed, and about six miles of streets paved. The Sanitary Engineer draws special attention to the excellent, economical and rapid work that has been done at Lucknow by Messrs. Lane Brown and Hewlett.

At Mirzapur the drainage works were nearing completion. They have been carried out with the greatest economy and praise is bestowed by the Sanitary Engineer on Mr. O'Brien, the municipal engineer, for the excellence of his work. A scheme for waterworks for the town is in contemplation.

The projects for the drainage of Budaun, Hathras, and Moradabad were nearing completion; and those for the drainage of Azamgarh, Firozabad, Khurja, and Huldwani were completed. Surveys are in progress in Hapur, Etawah, Saharanpur, and Gorakhpur, and were about to be undertaken in Amroha and Sambhal. The preparation of schemes for Muttra and Brindaban, Jaunpur, Ghazipur, Padrauna, and Bahraich has been assigned to Mr. Lane Brown. Experiments were carried out to ascertain the best methods of treating, and the time required in the processes for the treatment of domestic sewage and sullage, with encouraging results, and it is hoped that it will soon be possible to introduce septic tank latrines and bacteria beds which will give an effluent which can be discharged into open drains without nuisance.

The Sanitary Board held four meetings during the year when they approved projects, the estimates for which amounted to £125,677, an increase of 22 per cent. over the total of 1904 and of about 28 per cent. over the total of 1903.

The necessity for appointing an assistant to the Sanitary Engineer was admitted and Government addressed.

Punjab.—No information is given in the provincial report regarding the income of the municipal towns. At Lahore the daily consumption of water has risen rapidly in the last three years, due, it is believed, to leakage from the mains and to the extravagant irrigation of gardens. A complete scheme for the provision of waste meters was prepared and accepted by the Municipal Committee and the Sanitary Board, but nothing has been done owing to want of funds. An estimate for the extension of the well system at the head works to cost £5,220 was prepared for the Committee. Estimates for a conservancy tramway (£3,623) to carry night soil and refuse to a depôt at a distance from the city, and for improving the drainage outfall (£1,276) of the civil station, were prepared.

At Delhi good progress was made with the intramural drainage.

At Amritsar progress was made with the intramural drainage works; eleven projects to cost £6,553 for the drainage of different parts of the town were made over to the Municipal Committee. A committee was assembled to report on the best means of disposing of sewage at the outfall: it was resolved that land should be acquired to be let out to tenants. At Ambala the water-supply was increased by deepening five of the old wells; and the intramural drainage works were nearly completed. At Rawal Pindi the scheme for the construction of main intercepting drains and disposal works at a cost of £9,264 was in progress. At the new town,

Sargoda, the water-supply and drainage works were nearly completed. At Ludhiana an estimate of £26,667 for the construction of waterworks was sanctioned by the Local Government. At Multan the main drain and disposal works were well advanced. At Ferozepore and Muktesar the extramural drainage and disposal works were completed.

At Gujrat good progress was made with the extramural drainage and disposal works. A preliminary estimate for the drainage of Gurdaspur was prepared, and the detailed estimate for the Jagraon drainage works sanctioned.

At Simla arrangements were made to check the waste of water, new mains were laid down, and estimates for the construction of reservoirs to store storm water for flushing sewers were sanctioned. A Committee, appointed to enquire into the sanitary condition of the station, reported favourably on the water-supply and sewerage arrangements and recommended numerous improvements.

The provincial sanitary commissioner draws special attention to the gratifying increase in the amount of land used for the disposal of municipal sullage, &c., and to the higher price paid for sullage.

The Board met five times during the year. The following schemes were examined by them and submitted to the local Government for sanction. (1) Drainage scheme for Chiniot at a cost of £4,022; (2) Drainage scheme for Jagraon to cost £1,633; (3) Improvement of the drainage of Logarh gate at a cost of £1,848, and re-construction of drains, Lahori gate section, Amritsar city, at a cost of £685; (4) Water-supply scheme for Ludhiana at a cost of £26,667; (5) Metering the city and civil station pipe lines at Lahore, £1,495; and (6) Suburban drainage scheme for Delhi, £25,290. All except the last, which was under consideration, were sanctioned.

It was decided by the local Government to delegate to the Sanitary Board the power to sanction grants-in-aid from provincial revenues when necessary, within the limits of the sum allotted each year for the purpose, and the following instructions, along with a form drawn up by the Board calling for particulars of the financial condition, &c., of municipalities applying for aid, were issued to the district officers concerned.

(1) The Board shall examine the financial position of the local body concerned and decide whether it is possible for the project to be carried out entirely at the expense of the ratepayers with or without a loan.

(2) If it is decided that the project can be financed by a loan, the Board shall, in the case of all *large* municipalities, refer them to the instructions of Government regarding the raising of loans in the open market and recommend them to carry out the necessary negotiations; in the case of smaller municipalities the Board shall decide whether the cost of the project is or is not too heavy to be borne by the local body even with the assistance of a loan; in coming to a decision on this point the possibility of financing the project by a resort to increased taxation shall be carefully considered.

(3) If the local body is unable either by a loan, increased taxation or otherwise to finance the project, the Board shall decide whether the work is so important and useful that it ought not to be postponed.

North-West Frontier Province.—No sanitary work of great importance was carried out during the year, but many minor improvements were made in the various towns. At Peshawar where sanitary measures are energetically pushed forward, the following sums were spent: £688 on extension of the water-supply; £1,948 on drainage; £107 on paving streets. The sum derived from the sale of manure increased by £243 to £901.

Central Provinces and Berar.—The income of the headquarters' municipalities in 1904-05, excluding opening balances and special grants, was £88,237, of which 34·24 per cent. was spent on sanitation, including water-supply, drainage, conservancy, markets, slaughter houses, &c.; 5·77 per cent. on medical relief and epidemics (including 1·17 on plague) and ·16 per cent. on vaccination.

No original work of any importance was carried out during the year, and the money spent was devoted to the improvement or repair of existing water-supply works, the extension and renewal of drains and the like.

The Sanitary Board met at each district headquarters. The work carried out under their auspices consisted as usual in the improvement of village sites and surroundings, the construction of new walls and the repair of old ones.

Madras.—Including the presidency town there are 61 municipalities in Madras, but no information is furnished in the provincial report regarding their incomes or their expenditure on sanitary improvements, except that 39 failed to expend a fair share of the year's allotment. At Guntur the water-supply works were completed at a cost of £14,733 and opened on the 10th July. The water is brought by a masonry conduit from springs at the foot of the Kondavidu hills five miles from the town; at present the supply is equal to four gallons a head only.

At Coonoor the water-supply works estimated to cost £8,213 were opened in April. Estimates for the expenditure of £3,322 on extensions were sanctioned, and progress was made with the work. At Dindigul the scheme to supply water from the Oodukam valley by gravitation at a cost of £3,460 was completed in March. At Vellore the estimate was again revised to include compensation for the removal of three villages situated in the catchment area and now amounts to £25,168: pipes and other materials were delivered and the work was in progress. At Saidapet and Negapatam works of a more or less experimental character in connection with water-supply schemes were carried out. At Ootacamund stoneware pipes, &c., were ordered for the drainage works and work was commenced principally on the laying out of the sewage farm.

Schemes for the water-supplies of Salem and Coimbatore and for the drainage of Madura were examined during the year, and a number of additional schemes either complete with plans and estimates or in the form of reports with approximate estimates were submitted, the more important of which were the Ellore waterworks, Cocanada water-supply extension, Anantapur water-supply improvement, Masulipatam water-supply, Kottagiri water-supply, Periyakulam water-supply, Tuticorin water-supply extension, Negapatam drainage, Cuddapah drainage, and Madras water-supply improvement. It is proposed to substitute a masonry conduit for the existing open channel which conveys the Red Hills water to the City of Madras, and to provide filter beds and pumping power. The estimated cost of the scheme, which was being considered by the local Government, is £150,000.

The total sum assigned by District Boards to be spent on sanitation was £58,277, and nearly half of this sum was used during the last nine months of the year.

The Board examined the plans relating to 101 sanitary works estimated in the aggregate to cost £423,870. Of these 66 were finally approved, 21 were completed during the year, 26 were in progress and 18 were deferred for want of funds.

Bombay.—The income of the 162 municipalities in Bombay—the presidency town is excluded—in the year ending 31st March, 1905, was £456,665, and £124,192 was spent on the improvement of water-supply, drainage, and conservancy within municipal limits. No new scheme of water-supply or drainage was undertaken during the year, the reason given being the embarrassed condition of municipal funds on account of expenditure in connection with plague. The entire income of district and local Boards was £292,286, of which £18,644 was devoted to water-supply and drainage.

The Board met once during the year and considered the question of financial and technical assistance to be rendered to municipalities so as to stimulate progress in sanitary improvement. The Board submitted recommendations on the subject to the local Government.

At Ahmedabad nearly £100,000 has been spent on sewerage works which will serve rather more than a third of the total area and nearly half the total population. Further expenditure of £100,000 will apparently be necessary to complete the work. The water-supply works require extension and improvement at an estimated cost of £23,333. At Karachi the drainage extension works were commenced during the year. At Poona alterative projects for improving water-supply were considered, and detailed estimates for the comprehensive scheme including the city and cantonments and Kirkee were being prepared. The preparation of a revised scheme of drainage for Poona city was taken in hand. At Surat steps were taken

to improve the existing water-supply; and at Hyderabad the municipality is arranging to provide a new settling tank. Projects for completing the water-supply works and surface drainage of Pandharpur were being worked out.

Burma.—The income of all the municipalities in the province was £462,387, of which the following percentages were spent on sanitation—on water-supply 13, on drainage 8, on conservancy 12, on other sanitary works 12; but on account of the unusual outlay in Rangoon on the Hlawga water-supply project, the provincial Sanitary Commissioner suggests that a more correct idea of the average expenditure on sanitation will be obtained if the expenditure in the municipalities of the Pegu division is omitted. When this is done the percentages are on water-supply ·78, on drainage 3·80, on conservancy 12·16, and on other sanitary works 4·66. The total income of the town funds was £28,276, of which 21 per cent. was spent on conservancy, 2 per cent. on drainage, 4 per cent. on water-supply, and 18 per cent. on other sanitary works. Of the district funds, aggregating £316,542, rather less than 5 per cent. was devoted to purposes of sanitation.

At Rangoon the Hlawga well works were opened on the 22nd February, but the supply was not satisfactory and it was found that the expectations entertained of it would not be fulfilled. An expert committee was appointed and their report is reassuring; improved means of distribution will be required and increased pumping power, when, it may be hoped, that certain minor alterations will ensure an abundant supply.

At Moulmein the water-supply works were completed, but it appears that the piped supply has to compete with many defective wells. At Mandalay "the question of water-supply is still pending." Estimates for water-supplies were sanctioned for Akyab (£19,928), Rangoon Cantonment and Thonzé and prepared for Kyauktan, Thatôn and Meiktila. At Rangoon the question of providing an improved system of sewage disposal was carefully considered by the committee and an estimate of £34,695 was sanctioned by the local Government. The reclamation of land is proceeding. The provision of adequate house room for the growing population is becoming a serious matter. The remodelling of the existing building regulations has received consideration by the committee, but it is reported that they have not "approached the subject with that determination to face vested interests that is essential in dealing with a matter of this nature, if solid sanitary results are hoped for." Drainage schemes are in progress at Pegu and Insein. Preliminary estimates for drainage and conservancy schemes for Kyaiklat and Pyapon were prepared.

The Sanitary Board held two meetings during the year. At the first the constitution and functions of the Board were discussed, with the result that the constitution of the Board has been altered and its functions defined. In future it will consist of the Financial Commissioner, the Chief Engineer, the Sanitary Commissioner, and the Sanitary Engineer, the last named to be the Secretary. Commissioners, Deputy Commissioners, and Civil Surgeons will be *ex-officio* members when the Board meet in their division. The Board will meet at least four times a year and their functions will be "purely consultative." They are, however, required to report to Government any case of persistent disregard of their advice. At the second meeting of the Board the principal subject considered was proposed rules for the guidance of the Sanitary Engineer.

General Remarks.

Red Sea Pilgrim Traffic.—The Government of India notified in September, 1904, that, as the detention of pilgrims for ten days in observation camps at or near the ports of embarkation had proved costly and inconvenient to the pilgrims, it had been decided, with the concurrence of His Majesty's Government, that the period of observation should be reduced to five days at a central camp, from which, after satisfactory medical inspection and disinfection, pilgrims would be permitted to proceed to the Hejaz. The Haj was open to any resident in India, but embarkation was permitted from Bombay only; embarkation from Chittagong being discontinued because of the unlikelihood of pilgrims desiring to embark from this port if they could do so from Bombay. The warning given the previous year that intending pilgrims would be well advised to defer the fulfilment of their purpose until another year, was repeated.

In this report it is possible to notice the results of the pilgrim season of 1904-5 only, to which the orders referred to above relate; complete information for the season 1905-6 is not yet available. In view, however, of the change made in the conditions under which pilgrimage is to be permitted for the season 1906-7, and the fact that the orders were issued prior to the appearance of this report, it may here be mentioned that the conditions for the pilgrim season 1905-6 were the same as those for the season 1904-5, but for the season 1906-7, the Government of India notified at the end of September, 1906, that (1) no person shall be permitted to embark for a pilgrimage to Mecca except at Bombay; (2) all ships chartered for Jeddah shall be thoroughly cleansed and freed from rats by the Clayton process under the personal directions of the Port Health Officer; (3) ample hospital accommodation shall be provided on board; (4) before embarkation pilgrims shall be medically inspected and their clothes and baggage disinfected as in the case of third-class passengers on ordinary steamers; (5) the ships shall undergo further medical inspection both at Aden and at Perim; and (6) in the event of plague appearing on board a vessel arriving at Aden, telegraphic information shall be sent to Perim where the persons attacked shall be landed and placed in a plague camp; cases of the disease occurring between Aden and Perim shall be dealt with similarly, the ship being allowed to proceed to Kamaran.

The importance of the latest orders to the Moslem community in India lies in the fact that since the Government of India notification of the 20th February, 1897, suspending pilgrimage to Mecca, and the subsequent notification of the 20th November of the same year, permitting it, pilgrimage has every year since then been subject to medical observation of the pilgrims prior to embarkation. For the past two seasons that period has been restricted to five days only, and now medical observation prior to embarkation has been entirely abolished.

During the season 1904-5, a total of 12,449 pilgrims embarked in 15 ships at Bombay; of these the Kamaran report for that year records the arrival of 11,242, while the Haj report states that there arrived at Jeddah 11,820 Indian pilgrims, of whom 11,339 proceeded direct by pilgrim ships from Bombay and 481 adopted indirect routes. The pilgrimage of 1904-5 was a smaller one than that of the preceding year which was a Haj Akbar (grand pilgrimage).

The observation camp at Bombay was opened on the 20th October, 1904, the first ship leaving five days later and the last on the 13th January, 1905. During the voyage there were 16 deaths on eight ships, and 20 persons were landed at Aden, most of them on account of small-pox. During the period of quarantine at Kamaran 33 pilgrims died, six of them from small-pox, and 100 were admitted to hospital chiefly on account of acute and chronic respiratory diseases. The Vice-Consul remarks with satisfaction that the orders regarding the detention at Kamaran of sick pilgrims after the completion of the regulation period of quarantine have been relaxed and greater discretion was being exercised in the matter. In the Haj report it is stated that "the health of the pilgrims was perfect throughout the season," and that the sanitary condition of both Jeddah and Mecca has greatly improved within the last few years.

The pilgrims returned to Bombay between the 21st February and the 2nd September, 1905; in all 13,952 arrived in 25 ships. During the voyage to Bombay

there were 120 deaths on 10 ships, seven being due to small-pox; 11 ships furnished between them 35 cases of small-pox; of those on board infected ships, 325 were vaccinated, the rest refusing vaccination. The clothing and bedding of 5,648 pilgrims among whom small-pox appeared were disinfected before disembarkation was permitted; the other pilgrims who were found free from infectious diseases were landed immediately on arrival at Bombay and taken charge of by the Protector of Pilgrims who arranged for the despatch by rail of all pilgrims to their homes.

Malta Fever.—During the past year a considerable amount of original work has been done in connection with Malta fever and our knowledge of this disease, especially as regards its dissemination, has been much increased thereby. These researches have for the most part been carried out by the Mediterranean Fever Commission, working under the supervision of an advisory committee of the Royal Society.

The result of the Commission's work are here shortly summarised. The *M. melitensis* shows no sign of being able to lead a saprophytic life; outside the body it can retain its vitality for a long period, but it does not multiply. Many domestic animals—goats, cows, mules, horses, dogs, &c., are found to suffer naturally from the disease and of these the goat seems the most susceptible. It is found that about 50 per cent. of the milch goats in Malta suffer from the disease and about 10 per cent. (some apparently healthy) are excreting the specific microbe in the milk. Excretion in milk may continue for three months without any physical changes in the milk or any sign of ill-health in the goat. In this connection Zammit's test (the *milk* instead of the *blood* reaction with *M. melitensis*) is not only a good indicator of infection but is a surer test than the ordinary serum reaction that the micrococcus is being excreted in the milk. It was demonstrated that the milk of goats that are infected and have a marked blood reaction may not necessarily contain the micrococcus, and that, in the milk of a goat, the blood serum or milk of which has no agglutinative action, the micrococcus is not found. In the milk the excretion of the micrococcus (which has been shown to persist in the blood of a goat for seven months) may be intermittent. The goat is less susceptible to the disease than the monkey, and the monkey than man. In man the micrococci can be demonstrated in the peripheral blood in 68 per cent. of cases, but they are never very numerous in the blood; the smallest quantity of blood in which the micrococcus has been found is 4 c. mm., *i.e.*, in the proportion of one micrococcus to about 20,000,000 red corpuscles.

In the various experiments carried out by the Commission with expired air, saliva, sputum, sweat, scrapings of the skin and fæces, the micrococcus was never detected; we must, therefore, turn to the urinary passages in the hopes of finding an important channel of elimination. In the urine, the micrococcus is found from about the 15th day of illness till after convalescence is established and in this way hands, food, and dust may become infected. Elimination in urine may be intermittent or continuous. Ambulant cases are common, amounting to 10 or 15 per cent. of the entire native population in Malta; and the ambulant cases who are excreting the *M. melitensis* in their urine and are thus a possible danger to the community, constitute 1 or 2 per cent. This urine is infective to monkeys and goats.

There is a close correspondence between atmospheric temperature and incidence; on the other hand, incidence has no intimate connection with rainfall. Although Malta fever is least prevalent in the cold months, the number of cases which do occur in winter actually amount to about one-third of those recorded in the hot months—July, August and September—the season of greatest incidence.

Animals, chiefly monkeys and goats, have been infected by the respiratory and digestive tracts by using infected dust and infected food. With regard to the former, Bruce states that, as the experiments were with dust artificially contaminated with cultures and so with a very concentrated virus, there is no absolute proof that dust as it occurs under natural conditions ever conveys the disease to the healthy, and adds that "theoretically there seems to be danger from the scattering broadcast of such a virulent and resistant microbe, but it is possible that not a single case of infection occurs in this way." There is no such doubt about infection by the digestive tract. Monkeys fed on naturally infected goats' milk, *i.e.*, on the

ordinary milk of goats in the streets under natural conditions, have become infected. The injection of the virus under the skin of man or monkey or the application of the virus to a scratch gives rise to the disease. Infected dust or liquids applied to unbroken conjunctiva, nasal passages, pharynx or larynx may also lead to infection. Horrocks and Kennedy state that it is "extremely probable that human beings are infected by the bites of infected mosquitoes." They report three experiments which suggest the possibility of the disease being transmitted in this manner; yet many other experiments have been carried out on the same lines with negative results. Experiments, so far, are not conclusive and they do not prove that mosquitoes or other biting insects can infect man or animals. Davies and Johnstone seem to think that mediate contagion, *e.g.*, pollution of hands and food, play a significant part in dissemination. Horrocks says that infection cannot occur from contact with the cutaneous surface of a patient, unless that surface is contaminated with urine.

The incubation period is considered to be from 6 to 30 days or more. The general impression amongst Maltese medical men is that the usual incubation period is not more than 8 or 10 days. Horrocks gives the following figures: if infection is by subcutaneous injection or through a crack in skin or mucous membrane, the incubation period is from 5 to 7 days; if through unbroken mucous membrane, such as by feeding with infected goats' milk, the period may even extend to two months.

The prophylactic measures put forward chiefly concern urine, goats' milk and mosquitoes. Immediate and complete disinfection of clothing, bedding, bed-pans, and utensils soiled by Malta fever patients is recommended: urinals and latrines should be properly managed; milk pasteurised (68° C. for 10 minutes) or boiled; mosquitoes and infected goats destroyed; and Malta fever patients isolated in hospital.

Surgeons Ross and Levick, R.N., reasoning by a process of exclusion, have all along held that infection is carried chiefly by mosquitoes and other biting insects. Their work, appearing before the Commission's suspicions had been directed towards mosquitoes, was opportune and threw considerable doubt on the goats' milk theory at a time when it was almost generally believed that the Commission had found the key to the prophylaxis of Malta fever. These naval surgeons did not believe infection could be acquired through uninjured respiratory or digestive tracts. They drank water and goats' milk containing *M. melitensis* in large numbers and did not contract the disease. They pointed out that the disease was as prevalent as ever in Malta after care was being taken to sterilise milk; that the one regiment which did not boil its milk had the lowest admission rate; that in hospitals, where all milk was carefully sterilised, the incidence had increased. They criticised the food and dust experiments of the Commission on the grounds that the incubation periods were so very long; that the monkeys had to be fed for weeks before they contracted the disease as shown by the agglutination test, and even then there might be no sign of ill-health and the monkeys sometimes actually gain in weight; whereas, the inoculation of the minutest amount of virus under the skin gave rise to the disease in 6 days. They held that, when such enormous and unnatural quantities of infected material were used repeatedly over such a considerable length of time, lesions of mucous membrane may meanwhile have occurred and infection may not have occurred until a lesion had become inoculated. They maintain that the incubation period of natural infection (mosquitoes) is from 8 to 11 days.

It is recognised that there is more than one factor responsible for the spread of this disease and in the present state of our knowledge attention is directed chiefly to (1) goats' milk, (2) contamination—especially with urine—of hands, food and other articles and (3) mosquitoes. Of these the most important would seem to be goats' milk, and, up to the present, this is the only means by which we have little doubt the disease can be conveyed to man. As evidence of this the following instances collected by Bruce may be cited. (1) The introduction of Maltese goats into Rhodesia was followed by an outbreak of Malta fever. (2) In 1905 the S.S. "Joshua Nicholson" shipped 65 goats at Malta for export to America. The milk was drunk by the crew with the result that an epidemic of Malta fever broke out on board. (3) Strachan in the Orange River Colony blamed goats' milk for causing an outbreak of Malta fever at certain farms, and Birt found that the blood

of some of the goats of these farms gave the serum reaction with *M. melitensis*. (4) Forster isolated *M. melitensis* from the milk of one of the goats kept for supplying milk to a Malta fever stricken regiment at Ferozepore (Punjab). (5) Davies found that children in Malta who drank unboiled milk suffered four times as much as those who drank boiled milk.

Malta fever has during the past year been demonstrated to be endemic not only in India but also in South Africa and possibly in Egypt. Birt in the Orange River Colony, at first by a well controlled serum test, and subsequently by isolating *M. melitensis*, has shown that this fever is endemic in that region. Phillips has reported cases at Cairo: the serum reaction was positive in very high dilution, but no mention is made of the isolation of the micrococcus. In last year's report a full account was given of the history of Malta fever in India up to the work of Lamb proving the endemicity of the disease in this country. Recently Forster, at Ferozepore (Punjab), examined the herd of goats from which milk was being supplied to the 14th Sikhs, who had suffered considerably from the disease. He found that 10·5 per cent. of the goats gave the serum reaction and isolated the *M. melitensis* from the milk of one of them.

Reid reports great benefit from therapeutic inoculations, the dose of vaccine being regulated by observing the opsonic power of the blood, and suggests this method of inoculation for prophylaxis. Shaw (Commission) has drawn attention to the persistence of the living *M. melitensis* in the blood of goats for at least seven months and the bearing this persistence has upon the preparation of a therapeutic serum.

The Pasteur Institute, Kasauli.—The steady increase in the number of patients resorting to the Institute for anti-rabic treatment continued during the year ending August 8, 1906. A total of 1,262 persons presented themselves for treatment, of whom 117 were not treated, as there was satisfactory evidence that the animals that inflicted the bites were not rabid. Of the 1,145 persons treated, 342 were Europeans and 803 natives, compared with 307 Europeans and 570 natives in the previous year. Patients came from every province, from the native states of Rajputana and Kashmir, one from Sikkim, two from Ceylon and one from the Persian Gulf. Included in the total were 172 patients from the British army and 82 from the Native army. Of the total number treated there were seven failures only.

Besides anti-rabic treatment, bacteriological examinations of specimens, serum diagnosis, &c., were carried out, the number of cases thus furnishing material for examination being 880; further, in 277 instances experiments were carried out to prove the existence or otherwise of rabies in animals dead with suspicious symptoms.

The duty of preparing sera was transferred from the Pasteur Institute to the Central Research Institute in December, 1905; between the 9th August and the end of November, 1905, 410 bottles of antivenene and 312 bottles of antidiphtheritic serum were issued from the Pasteur Institute.

Research Laboratories.—The *Central Research Institute* at Kasauli is situated well away from other buildings in the cantonment. The Institute consists of ten substantial stone buildings; the main one, which was formerly an official residence, has been considerably altered to adapt it for the purposes of a laboratory, while the others have been built for the various purposes for which they are required. The main building has a large hall running through the centre and is surrounded by a wide verandah; the flooring is of glazed tiles; in all the rooms gas light is available and in some electric light as well. The building contains about 21 rooms which have been allotted for various purposes, such as microscopic work, photography, library, offices, &c. The subsidiary buildings, or blocks, are used for housing animals, preparing sera and storing chemicals and spare apparatus; one block is fitted up with a 10½ H.P. oil engine, a dynamo, an electric storage battery of 56 cells, a freezing machine and cold storage room, and another with a Mansfield gas installation; there are also quarters for 12 servants. A piped water-supply has been laid on to four of the ten buildings. The Institute has been fully equipped with all necessary apparatus and can accommodate six to eight workers. Two officers of the Indian Medical Service have received a two months' course of instruction in technique, qualifying them for investigations connected with malaria, *kala azar* and blood diseases generally.

The *King Institute of Preventive Medicine*, at Guindy, about six miles from Madras City, is divided into two sections—the vaccine and the bacteriological. The buildings occupy an extensive site; on the east are the bacteriological laboratories, animal house and experimental sewage disposal works; in the centre the numerous smaller buildings of the vaccine section, and on the west the quarantine and isolation sheds of the vaccine section and two laboratory blocks with stables designed for serum work. In the grounds are quarters for the superintendent, the deputy superintendent and a European subordinate. The chief laboratories are located in a large building with open corridors and wide verandahs. The laboratories and the rooms of the manufacturing block of the vaccine section are floored with smooth Cuddapah slab and have white glazed tiled walls, while the fittings are of polished black stone or of glass; the floors of each stall in the calf sheds consist of a single partially polished Cuddapah slab which is kept scrupulously clean day and night by men told off for that purpose. The laboratories are fitted with electric fans worked by a gas engine and dynamo. The water is supplied under pressure from cisterns on the roof, the pumping station being situated at no great distance. The Institute has been fully equipped for preparing vaccine and conducting the bacteriological work of the presidency and also serves as a centre of training for sanitary assistants, vaccinators and plague inspectors to whom both practical and theoretical instruction is imparted. The laboratories are available for the instruction of officers and the carrying out of research work by them.

The *Pasteur Institute for Southern India* is located at Coonoor. Besides the main building which stands in a large compound, there are the necessary outbuildings which include quarters for a hospital assistant and servants, stables for horses, houses for rabbits, and godowns for stores and apparatus. The main building is a two-storied one, with a central corridor running from end to end. On the ground floor are the work rooms (rooms for the preparation and preservation of the virus, patients' waiting and inoculation rooms, surgery, &c.) and clerks' office: on the upper floor, on one side, are the director's office, the library and store rooms, and on the other, residential quarters which will probably be allotted to the assistant director. Gas and water pipes are to be fitted to the building which is nearing completion; it is expected that the Institute will be ready to receive patients for treatment in February next.

• *Facilities for Research or Instruction at Laboratories.*—With a view to supplementing the work of the bacteriological laboratories in the investigation of Indian diseases, it has been arranged that officers of the Indian Medical Service who may volunteer, and officers of the Royal Army Medical Corps, who are recommended by the Principal Medical Officer in India, may be allowed to proceed to a laboratory for a period of three to six months for the purpose of prosecuting research already commenced or for instruction in technique, provided local arrangements can be made for the conduct of routine duties during their absence. While at a laboratory, officers will draw their ordinary pay, less any local allowances, and will be granted travelling allowances; no deputation allowance will be admissible.

Special Enquiries.—In addition to routine work at the bacteriological laboratories, special enquiries have been commenced with reference to typhoid fever in India, dysentery in jails and lunatic asylums, and malaria in the Presidency division of Bengal, and the inquiry into the etiology of *kala-azar* has been continued.

Typhoid Fever.—In March, 1906, the staff of the Central Research Institute, Kasauli, commenced an investigation in connection with the etiology and spread of enteric fever in India. Work was begun with material available in Kasauli and its vicinity, and during the winter of 1906-7 the investigations are to be conducted in the cantonment of Meerut, the staff of the Central Research Institute being strengthened temporarily by the deputation of specially selected officers to assist in the enquiry.

Dysentery.—This is the most serious cause of mortality in Indian prisons, and it has been known for many years that the term dysentery in the returns included several diseases presenting nearly identical signs and symptoms although arising from different causes. In order to further investigate the matter the Government of India placed Captain W. C. H. Forster, I.M.S., on special duty under the Sanitary Commissioner, to investigate the causation, prophylaxis and treatment of dysentery

in the prisons and lunatic asylums of India. Captain Forster has been authorized to visit a certain number of jails in the several provinces, and also lunatic asylums, and carry out researches therein. The results of Captain Forster's investigations will, it is hoped, add to the existing knowledge of one of the most fatal of tropical diseases.

Malaria.—The Government of Bengal recognised in their Resolution No. 1379-Medical, dated the 26th March, 1906, that over a large part of the province, and particularly in the Presidency division, a main cause of ill-health is the obstruction of drainage. A complete remedy was not held to be possible, but it was considered certain that in many places the conditions could be greatly ameliorated by the execution of drainage projects which could be carried out without excessive expenditure. A local committee of three members was appointed to visit the districts of the Presidency division (1) to ascertain what areas are specially unhealthy; (2) to investigate the cause of the prevalent sickness and in particular to determine how far this prevalence is due to obstructed drainage; (3) to consider if a drainage scheme is practicable; and (4) to prepare a list of practicable drainage schemes in their order of urgency. To assist the committee with expert knowledge the services of Captain G. E. Stewart and Lieutenant A. H. Proctor, I.M.S., have been lent temporarily to the local Government.

Kala Azar.—Contributions to our knowledge of the Leishman-Donovan body are conspicuously absent from the parasitological literature of the year, and it appears as if observers were awaiting the discovery of the extra-corporeal stage of the parasite to renew their labours.

The reports for 1903 and 1904 contain a history of the discovery of the parasite and of the growth of knowledge concerning it, and the present time seems opportune to summarize what is now known regarding it.

The prominent clinical features of *kala azar* are a characteristically irregular temperature, progressive cachexia and splenic enlargement, conditions which have given rise to the names "malarial cachexia," "cachectic fever," and "tropical splenomegaly." In the early stages of the disease it sometimes resembles enteric fever, but the febrile attacks are often followed by periods of apparent perfect health; as the disease progresses profound cachexia supervenes; diarrhœa, *cancrum oris*, *cancrum vulvæ*, transient œdemas, petechial eruptions, pigmentary changes and ulcers of the skin are of more or less constant occurrence. The disease is common and particularly severe in Assam, where it has long been well known clinically, but it has a wide distribution within the tropics and cases have been reported among other countries from Africa, Malaysia and China. The parasite of *kala azar* is, as we have seen, morphologically identical with the parasite of the chronic granuloma of the skin known as Delhi boil; whether there is any difference between the parasites, as might be expected from the geographical distribution of the two diseases, the future will, no doubt, disclose.

The parasite of *kala azar* is a circular body, 2—3μ in diameter, formed of a clear homogeneous cytoplasm, in which are embedded close to the periphery two conspicuous chromatin masses resembling the chromatin masses of a trypanosome. The smaller mass is a blepharoplast from which there often stretches a short "tail" of chromatin. The existence of double forms makes it probable that the parasites reproduce themselves in the body by binary fission. Circular bodies giving rise by multiple fission to from 3 to 8 parasites occur, but the stages of their formation have not yet been completely followed. The parasite is nearly always embedded in the cytoplasm of some kind of cell, generally in the endothelial cells of the viscera, but also in leucocytes. Large macrophages, probably of endothelial origin, containing as many as two hundred parasites are found in cases of *kala azar* and of Delhi boil.

In *kala azar* the parasites are present in enormous numbers in the spleen, liver and bone-marrow, and they are also found in the intestinal walls, in the lymphatic glands, kidneys and testicles. In advanced cases, they are to be found in the leucocytes in the peripheral circulation, and in petechial hæmorrhages in the brain membranes. They are present in granulation tissue wherever it occurs, and in papules of the skin. In Delhi boil the parasites are packed in the cells of the granulation tissue in such numbers as to give rise to an appearance under the microscope of a section of the spleen in *kala azar*.

It was shown by Rogers that, if splenic blood, taken from a case of *kala azar*, is prevented from clotting by the addition of citrate of soda solution, and is kept at a temperature of 22° C.-24° C., the parasites enlarge, the protoplasm becomes granular, and the chromatin masses assume a more central position: repeated fission then occurs and most of the forms develop a thick flagellum, those parasites resembling a typical flagellate. The question now is, "what happens next?"

Researches regarding the extra-corporeal life of the parasite are being pursued by Captain Patton, I.M.S., who has been attached to the King Institute at Guindy for the purpose of this investigation. It was found by Christophers and by Donovan that in certain cases a considerable number of the parasites was present in the leucocytes of the peripheral blood, and it was suggested by the former that this distribution might be concerned in the dissemination of the disease. Captain Patton has found that the parasite is frequently found in the peripheral blood—so frequently that an examination of the blood is of considerable diagnostic value, and that the number of parasites in the blood may be very great, as many as 80 being found in one case in a single film. He has found that, although ordinarily in *kala azar* there is leucopenia, when diarrhœa is present there is almost always leucocytosis with the abundant presence of parasites in the peripheral blood. Founding a hypothesis upon this fact and upon the process of development *in vitro*, Captain Patton conducted a long series of feeding experiments with mosquitoes, lice and bugs, and found that parasites could be recovered from the gut of the bug four days after feeding and that they showed in some cases the changes characteristic of development.

It is as yet doubtful if this fact indicates the bug as the carrier of *kala azar*; and Rogers' experiments, showing that the bodies develop best in an acid medium, do not incriminate the bug more than other blood-sucking insects. For the present we must be content to know that the work of Rogers and Patton favours the view that infection may be carried from cases in which the peripheral circulation is loaded with parasites by a blood-sucking insect. The fact that in cases in which diarrhœa is severe the peripheral circulation contains many parasites throws a new light upon Bentley's statement that dysenteric cases are chiefly concerned in the spread of the disease.

Standing Committee on Enteric Fever in India.—In July, 1906, the Government of India, on the recommendation of His Excellency the Commander-in-Chief, approved the formation of a standing committee for the purpose of investigating and advising on the incidence of enteric fever in India and its prophylaxis. The committee is composed of the Principal Medical Officer, His Majesty's Forces in India, as President (*ex-officio*), a Vice-President and five members drawn from medical officers in military employ, with the Sanitary Officer, Army Headquarters, as member and Secretary. The Government of India decided that their Sanitary Commissioner and the Director of the Central Research Institute, with Major G. Lamb, I.M.S., and Captain E. D. W. Greig, I.M.S., should also be members of the committee. The committee held their first meeting at Simla on July 31, 1906, and following days, His Excellency the Commander-in-Chief opening the proceedings in person, and the second meeting, also at Simla, on October 17, 1906, and subsequent days.

Scientific Memoirs.—Since the issue of the last report the following memoirs have been published:—No. 21, "On the Standardisation of Anti-typhoid Vaccine," by Captains G. Lamb and W. H. C. Forster, I.M.S.; No. 22, "Mediterranean Fever in India; Isolation of the Micrococcus Melitensis," by Captain G. Lamb, I.M.S., and Assistant Surgeon M. Kesava Pai; No. 23, "The Anatomy and Histology of Ticks," by Captain S. R. Christophers, I.M.S.; No. 24, "On a Parasite found in the White Corpuscles of the Blood of Palm Squirrels," by Captain W. S. Patton, I.M.S.; No. 25, "On the Importance of Larval Characters in the Classification of Mosquitoes," by Captain S. R. Christophers, I.M.S.; No. 26, "Leucocytozoon Canis," by Captain S. R. Christophers, I.M.S.

JOHN T. W. LESLIE, Lieutenant-Colonel, I.M.S.,
Sanitary Commissioner with the Government of India.
